The **sternal line of pleural reflection** is that along which the costal pleura leaves the ventral thoracic wall to become the mediastinal pleura. The lines differ somewhat on the two sides, and in both cases show a tendency to deviate to the left (Fig. 839, p. 1083). In the vicinity of the manubrium sterni the two pleural sacs are separated from each other by an angular interval. The lines of reflection at the superior thoracic aperture or inlet correspond to the sterno-clavicular joints. From those points the lines, as they are traced downwards, converge behind the manubrium, until at last they meet at its inferior border. There the two sacs come into contact with each other, and the lines of reflection coincide. Thence they proceed downwards, on the back of the body of the sternum, with a slight deviation to the left of the median plane, until a point immediately above the level of the sternal attachments of the fourth costal cartilages is reached, and there the two sacs part company. The line of reflection of the *right pleura* is continued downwards in a straight line to the xiphoid process, where the sternal reflection-line passes into the right diaphragmatic reflection-

line. Opposite the sternal attachment of the fourth costal cartilage the reflection-line of the *left pleura* deviates laterally, and is continued downwards at a variable distance from the right pleura. A small triangular area of pericardium is thus left uncovered by pleura, and therefore in direct contact with the ventral chest-wall. Leaving the sternum, the reflection-line of the left pleura passes downwards, parallel and close to the left margin of the sternum, dorsal to the fourth intercostal space, the fifth costal cartilage and the fifth intercostal space, to the sixth costal cartilage. There it turns laterally and downwards, and passes into the diaphragmatic reflection-line of the left side.

From the back of the sternum the *right pleura* is reflected, in the superior part of the chest, on to the remains of the thymus, the right innominate vein and the superior vena cava, and, at a lower level, directly on to the ventral aspect of the pericardium. The *left pleura* is reflected from the back of the manubrium sterni on to the left innominate vein and the aortic arch, and, at a lower level, directly on to the ventral side of the pericardium.

The **diaphragmatic line of reflection** is that along which the pleura leaves the thoracic wall and is reflected on to the thoracic surface of the diaphragm. This reflection takes place along a curved line, which, except as it approaches the vertebral column, is placed a short distance above the inferior border of the thoracic wall. It differs somewhat on the two sides of the body.

On the *left side* the diaphragmatic line of reflection proceeds downwards along the ascending part of the sixth costal cartilage, crosses the ventral end of the sixth intercostal space and the descending part of the cartilage of the seventh rib (Fig. 841). Still continuing to pass downwards, it crosses the eighth costal arch at the junction between its cartilaginous and bony portions. This is a fairly constant relation on both sides of the body, and it should be noted that a vertical line—the mamillary line,—drawn downwards from the nipple of the breast, intersects the line of pleural reflection, close to the point where it presents this relation to the eighth costal arch. Beyond that point the line of diaphragmatic reflection is carried downwards and laterally across the extremities of the bony portions of the ninth and tenth ribs. As it crosses the tenth rib, or, it may be, as it proceeds across the tenth intercostal space, the line of pleural reflection reaches its lowest point, and it is important to observe that this point lies in the mid-lateral line (*i.e.* in a vertical line drawn on the side of the chest, midway between vertebral column and sternum). Thence, as it curves dorsally towards the vertebral column, it passes slightly upwards. Thus it cuts across the eleventh rib and reaches the twelfth rib. The relation which it presents to the twelfth rib varies in accordance with the length of that rib. When the last rib is not abnormally short the pleura clothes its medial half, and the line of reflection falls below that portion of the rib, so as to reach the vertebral column, midway between the capitulum of the last rib and the transverse process of the first lumbar vertebra (Fig. 842). There, therefore, the line of diaphragmatic reflection falls below the inferior border of the thoracic wall; and this is a point of practical importance, because in operations upon the kidney the incision cannot be carried above the level of the transverse process of the first lumbar vertebra and the lateral lumbo-costal arch without the risk of wounding the pleura.

On the *right side* the line of diaphragmatic pleural reflection differs from that on the left chiefly ventrally (Fig. 839, p. 1083). There it passes at a lower level, and proceeds laterally and downwards from the dorsum of the xiphoid process along the dorsal aspect of the seventh costal cartilage, and then behind the eighth costal arch, as a rule at the same point as on the left side, viz., the junction of its cartilaginous and bony parts. From that point to the vertebral column the relations are so similar to those of the left side that a separate description is unnecessary.

It is commonly stated that the left pleural sac reaches a lower level than the right. In certain cases there is no doubt that it does, but this condition is by no means the rule. In those cases where the two pleural sacs do not reach the same level at their lowest points, it is sometimes the right and sometimes the left pleura which oversteps the mark.

As already stated, the lowest point which the pleura attains is usually found, on both sides, in the mid-lateral line where the diaphragmatic reflection-line crosses the tenth rib or the tenth intercostal space. That point can be very readily ascertained on the surface by drawing a horizontal line round the trunk at the level of the lowest part of the extremity of the spinous process of the first lumbar vertebra, and noting where it is intersected by the mid-lateral line. In the majority of cases the point of intersection will correspond with the lowest part of the pleural sac. Another horizontal line opposite the

spine of the twelfth thoracic vertebra will give the level of the diaphragmatic pleural reflection in the mamillary line.[1]

Along the line of the diaphragmatic reflection a strong fascia passes from the uncovered part of the diaphragm, and from the costal cartilages to the surface of the costal pleura, so as to hold it firmly in its place. It may be termed the **phrenico-pleural fascia.**

MEDIASTINUM.

The term mediastinum is applied to the interval between the mediastinal portions of the two pleural sacs. *Ventrally* it is bounded by the sternum, and

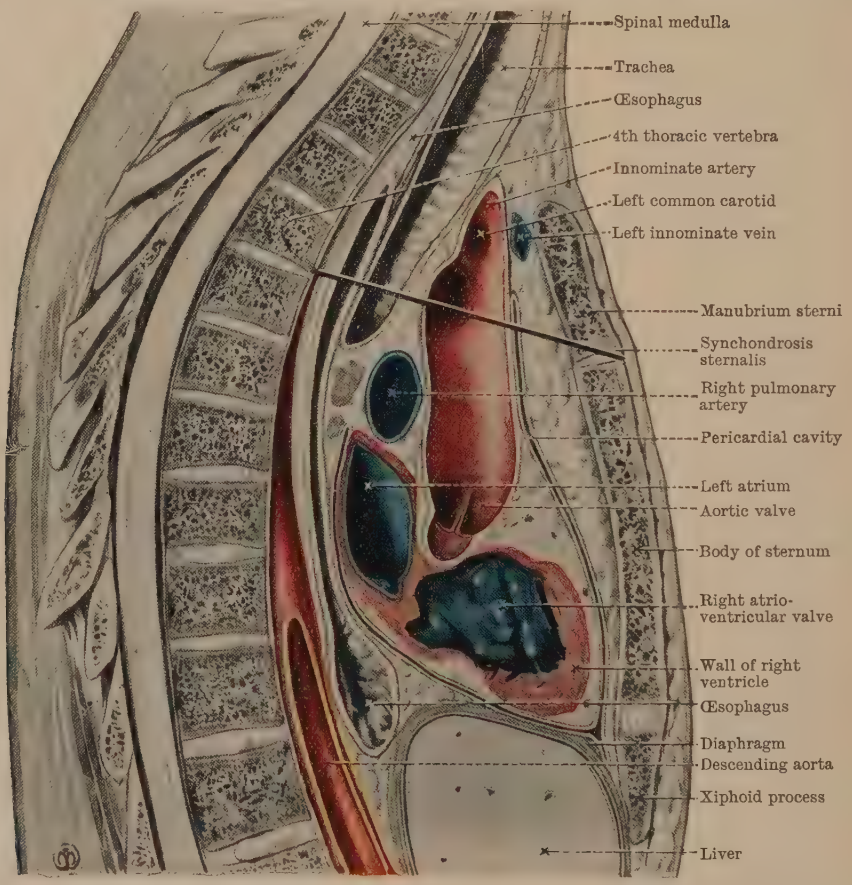

FIG. 843.—SAGITTAL SECTION THROUGH THE THORAX OF AN OLD MAN. The superior border of the manubrium sterni and the bifurcation of the trachea are lower than in the average adult.

dorsally by the vertebral column. It is customary to subdivide this space in a purely arbitrary manner into four portions, termed respectively the superior or cranial, the ventral or anterior, the middle, and the dorsal or posterior part, according to the relations which they present to the pericardium.

The **superior mediastinum** is that part of the general area which lies above the level of the pericardium. Its boundaries are as follows:—*Ventrally*, the manubrium sterni, with the attached sterno-hyoid and sterno-thyreoid muscles; *dorsally*, the bodies of the first four thoracic vertebræ; *below*, an imaginary and oblique plane, which extends from the inferior border of the manubrium sterni to

[1] The above description represents the average results which have been obtained from the study of the pleura in a large number of subjects, eight of which were specially hardened by formalin or other re-agents for the purpose. For many of the dissections I have to thank my former assistant, Dr. H. St. J. Brooks, and for others I am indebted to Professor C. J. Patten of Sheffield.—D. J. C.

the inferior border of the fourth thoracic vertebra; *laterally*, the mediastinal pleura.

Within the superior mediastinum are placed (1) the aortic arch and the three great arteries which spring from it; (2) the innominate veins and part of the superior vena cava; (3) the trachea, œsophagus, and thoracic duct; (4) the phrenic, vagi, and cardiac nerves, and the left recurrent nerve; (5) the thymus.

The **middle mediastinum** is the wide part of the area which contains the pericardium, and lies below the superior mediastinum. In addition to the pericardium and its contents the middle mediastinum contains the phrenic nerves and their accompanying vessels.

The **ventral mediastinum** is that part of the interpleural region which lies between the pericardium dorsally and the body of the sternum ventrally. In its superior part this region can hardly be said to exist, seeing that there the two pleural sacs come into contact with each other on the ventral aspect of the pericardium; but below the level of the sternal ends of the fourth costal cartilages the left pleura falls short of the right pleura, and an interval is apparent. The only contents to be noticed in the ventral mediastinum are a few lymph glands and some areolar tissue, in which ramify some lymph vessels, and some minute twigs from the internal mammary artery.

The **dorsal mediastinum** is that part of the interpleural region which is situated dorsal to the pericardium. It may be regarded as an inferior continuation of the more dorsal part of the superior mediastinum, and many of the structures in the one are prolonged into the other. The arbitrary superior limit of the dorsal mediastinum is the inferior border of the fourth thoracic vertebra. *Ventrally* it is bounded by the pericardium and the vertical part of the diaphragm. *Dorsally* it is limited by the bodies of the last eight thoracic vertebræ and *on each lateral side* by the mediastinal pleura. It contains the descending thoracic aorta, the aortic intercostal arteries, the azygos, hemiazygos and accessory hemiazygos veins, the thoracic duct and the œsophagus, with the two vagi.

Structure of the Pleura.—The pleura on each side is a closed sac, and, like other serous membranes, is attached to the wall of the cavity which it lines and to the surface of the viscus which it covers. It is composed of a thin connective-tissue stratum, in which bundles of fibres cross each other in various directions, and intermixed with which there is a considerable quantity of elastic tissue. On the internal surface of this there is a continuous coating of thin endothelial cells placed edge to edge. The pleura so formed is attached to the parts which it lines and invests by a small amount of areolar tissue termed the **subserous layer**. In the case of the pulmonary pleura the subserous tissue is continuous with the areolar tissue in the substance of the lung, and this accounts for the tight manner in which the membrane is bound down.

The pleura is plentifully supplied with blood. This is conveyed to it by minute twigs from the intercostal arteries, the internal mammary artery, and the bronchial arteries. Lymph vessels are also particularly abundant in the pleura and in the subserous layer, and it is by these that excess of fluid is conveyed from its cavity. Stomata, which have been described, are artificial apertures in the epithelium and are not connected with the lymphatic vessels.

PULMONES.

The Lungs.—When healthy and sound each lung lies free within the corresponding pleural cavity, and is attached only by its root and the ligamentum pulmonale. It is uncommon, however, in the dissecting-room, to meet with a perfectly healthy lung. Adhesions between the pulmonary and parietal layers of pleura, due to pleurisy, are generally present.

Like the cavities in which they are placed, the two lungs are not precisely alike. The right lung is slightly larger than the left, in the proportion of about 11 to 10. The right lung is also shorter and wider than the left lung. This difference is due partly to the great bulk of the right lobe of the liver, which forces the right cupola of the diaphragm to a higher level than the left cupola, and partly to the heart and pericardium projecting more to the left than to the right, thus diminishing the width of the left lung.

The lung is light, soft, and spongy in texture; when pressed between the finger and thumb it crepitates, and when placed in water it floats. The elasticity of the pulmonary tissue is very remarkable. A striking demonstration of this is afforded when the thoracic cavity is opened, and the atmospheric pressure acting upon the interior and exterior of the lung is equalised. Under these conditions the organ immediately collapses to about one-third of its original bulk, and it becomes impossible in such a specimen to study its proper form and dimensions.

The surface of the adult lung presents a mottled appearance. The ground

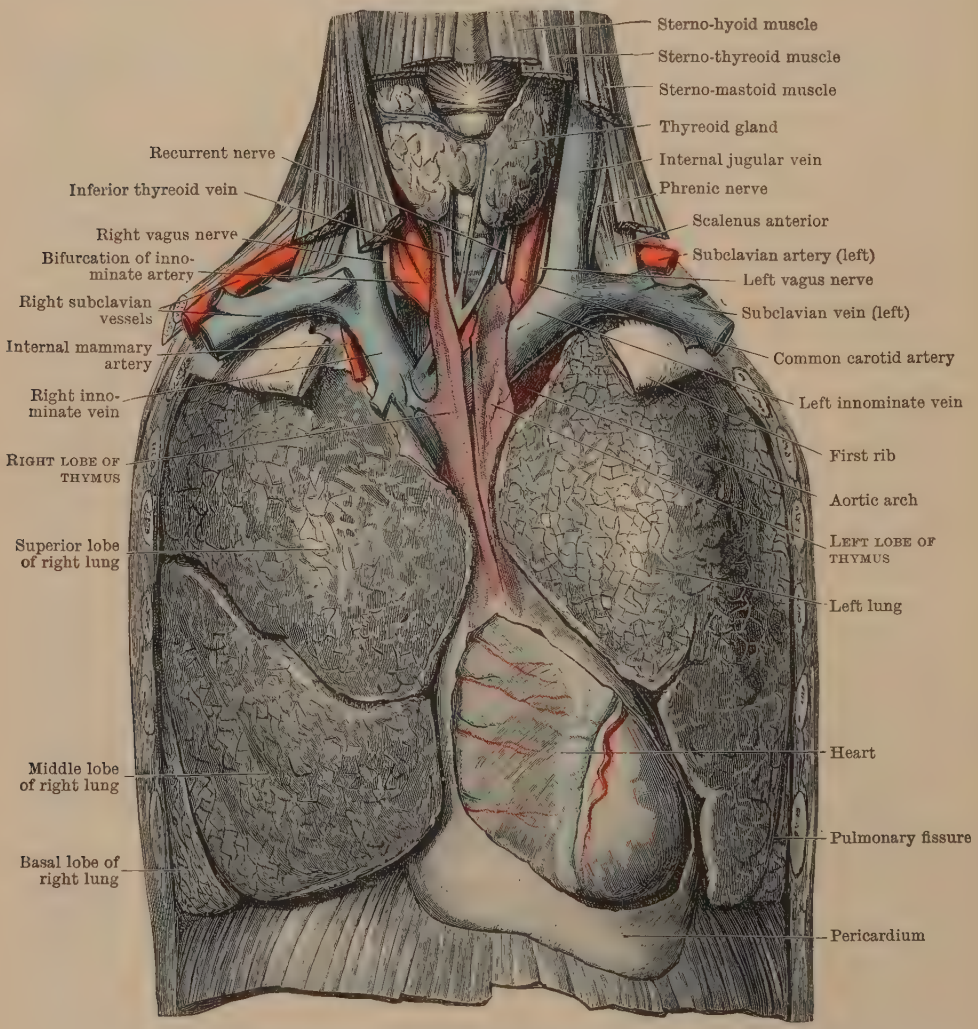

Fig. 844.—Dissection of Thorax and Root of the Neck from the front to show the relations of the Lungs, Pericardium, and Thymus.

colour is a light slate-blue, but scattered over this there are numerous dark patches of various sizes, and also fine dark intersecting lines. The coloration of the lung differs considerably at different periods of life. In early childhood the lung is rosy-pink, and the darker colour and the mottling of the surface, which appear later, are due to the pulmonary substance, and particularly its interstitial areolar tissue, becoming impregnated, more or less completely, with atmospheric dust and minute particles of soot.

At every breath foreign matter of this kind is inhaled, but only a small proportion of it reaches the lung tissue. The greater part of it becomes entangled in the mucus which coats the mucous membrane of the larger air-passages, and is gradually got rid of along with the mucus through the activity of the cilia attached to the lining epithelium. By the

constant upward sweep of these a current towards the pharynx is established. The fine dust and soot particles which reach the finer recesses of the lungs, and ultimately the interstitial tissue, are partly conveyed away by the lymph vessels to the bronchial glands, which in consequence become, in many cases, quite black. The colour of the lung, therefore, depends, to some extent, upon the purity of the atmosphere which is inhaled, and it thus happens that in coal-miners the surface of the lung may be very nearly uniformly black.

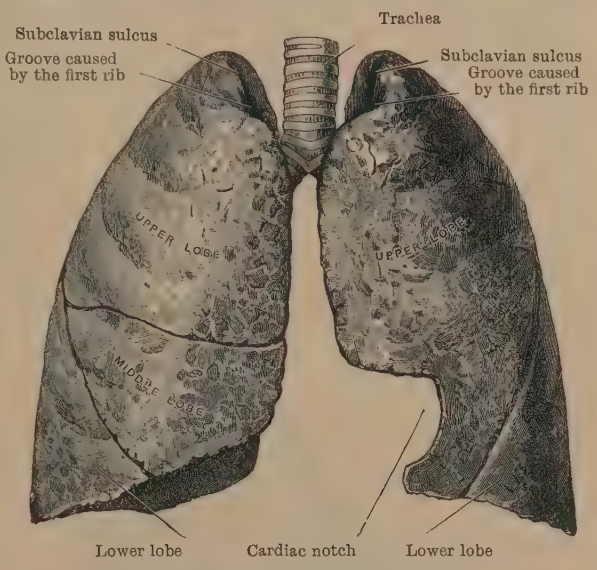

FIG. 845.—THE TRACHEA, BRONCHI, AND LUNGS OF A CHILD, HARDENED BY FORMALIN INJECTION.

The fœtal lung differs from the lung of an individual who has breathed. After respiration is fully established, the lung soon comes to occupy almost the whole space allotted to it in the pleural cavity; in the fœtus, on the other hand, the lung is packed away at the dorsal aspect, and occupies a relatively much smaller amount of space in the thoracic cavity. Further, it is firm to the touch, and sinks in water. It is only when air and an increased supply of blood are introduced into the lung that it assumes the soft spongy and buoyant qualities which are characteristic of the adult lung.

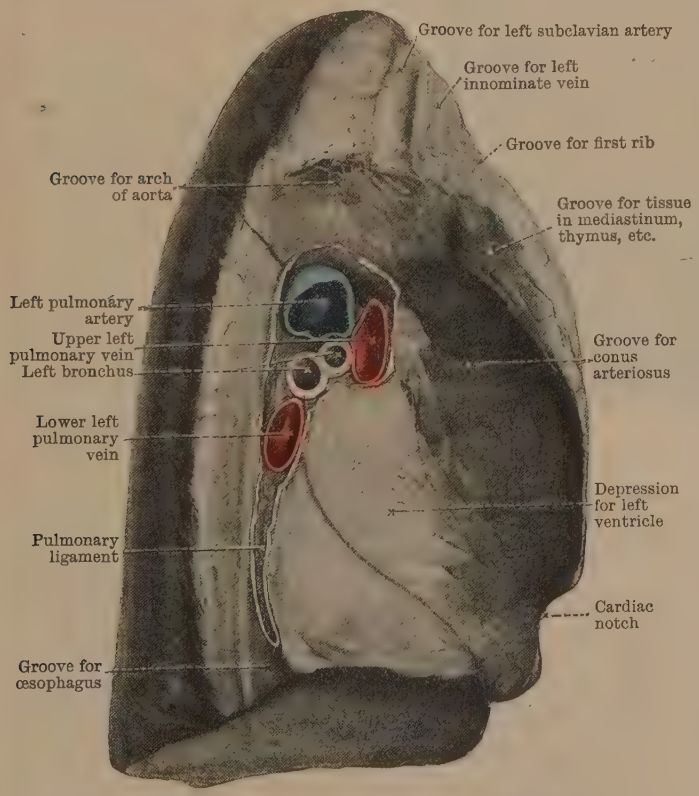

FIG. 846.—MEDIAL SURFACE OF A LEFT LUNG HARDENED *IN SITU*.

Form of the Lungs.—The lungs are accurately adapted to the walls of the pleural chambers in which they are placed, and in the natural state they bear on the surface impressions and elevations which are an exact counterpart of the irregularities on the walls of the cavity in which they lie.

When care has been taken to harden it *in situ*, each lung presents for examination an apex, diaphragmatic, mediastinal, and costal surfaces, and ventral (anterior) and inferior borders.

The **apex of the lung** is blunt and rounded, and rises above the level of the oblique first costal arch to the full height of the cupula pleuræ. It therefore

protrudes, above, through the superior aperture of the thorax, into the root of the neck. The subclavian artery arches laterally on its medial and ventral aspects a short distance below its summit, and a groove, the *subclavian sulcus*, corresponding to the vessel, is apparent upon it. At a lower level on the apex of the lung a shallower and wider groove upon its medial and ventral aspects marks the position of the innominate vein. Although these vessels impress the lung they are separated from it by the cupula pleuræ.

As examined from behind the apex of the lung usually extends as high as a line drawn from the highest portion of the acromion of the scapula to the inferior or caudal border of the spinous process of the seventh cervical vertebra. It may, however, be slightly higher or lower than this level.

The lateral limit of the apex of the lung, and consequently of the pleura, is medial to the superior angle of the scapula. The line is then continued across the supra- and infraspinous fossæ obliquely to reach a point somewhat lateral to the line of the inferior angle of the scapula.

Pulmonary ligament

FIG. 847.—THE MEDIAL SURFACE OF A RIGHT LUNG HARDENED *IN SITU*.

Clinically, percussion of the lung would appear to give resonance areas over a more extensive area, especially laterally, than is here set forth, but this is probably due to the differences between the smaller internal concentric circle formed by the first rib, which bounds this part of the lung, and the larger external one formed by the surface of the body itself.

The **diaphragmatic surface**, or base of the lung, presents a semilunar outline, being curved around the base of the pericardium. It is adapted to the thoracic surface of the diaphragm, and is consequently deeply hollowed out. As the right cupola of the diaphragm passes further upwards than the left, the basal concavity of the right lung is deeper than that of the left lung. Laterally and dorsally, the diaphragmatic surface of each lung is limited by a thin salient margin, called the *inferior border* or margin, which extends downwards for some distance in a narrow pleural recess, the *phrenico-costal sinus*, between the diaphragm and the chest-wall. This inferior border of the lung extends further downwards on the lateral side and dorsally than it does ventrally, but it falls considerably short of the bottom of the phrenico-costal sinus. Thus, after expiration, it reaches the inferior border of the sixth rib in the mamillary line; the eighth rib, in the axillary or mid-lateral line; whilst dorsally it proceeds medially along a straight horizontal line so as to reach the vertebral column at the level of the extremity of the spine of the tenth thoracic vertebra. During respiration the thin inferior border moves freely in a vertical direction within the phrenico-costal sinus, but even after the deepest breath it never reaches the extreme lower limit of this recess.

The diaphragmatic surfaces of the lungs establish important relations with certain of the viscera which occupy the costal zone of the abdominal cavity, the diaphragm alone intervening. Thus the diaphragmatic surface of the right lung rests upon the right lobe of the liver; whilst that of the left lung is in relation to the left lobe of the liver, the fundus of the stomach, the spleen, and in some cases to the left colic flexure.

The **costal surface** is extensive and convex. It is accurately adapted to that part of the wall of the pleural cavity which is formed by the costal arches and the intervening intercostal muscles, and it presents markings corresponding to these. Thus the imprint of the ribs appear as shallow oblique grooves, while the intercostal spaces show as elongated intervening bulgings.

The **mediastinal surface** presents a smaller area than the costal surface. It is applied to the mediastinal septum, and presents markings in accordance with the inequalities upon this (Figs. 846 and 847). Thus it is deeply hollowed out in adaptation to the pericardium upon which it fits. This pericardial concavity comprises the greater part of the mediastinal surface, and owing to the greater projection of the heart to the left side, it is much deeper and more extensive in the left lung than in the right lung. Above and dorsal to the pericardial hollow is the **hilum** of the lung. This is a wedge-shaped depressed area, within which the blood-vessels, nerves, and lymph vessels, together with the bronchus, enter and leave the organ. Amidst these structures there are also some bronchial glands. The hilum is surrounded by the reflection of the pleura from the surface of the lung on to the pulmonary root. Dorsal to the hilum and pericardial area there is on each lung a narrow strip of the mediastinal surface of the lung which is in relation to the lateral wall of the dorsal mediastinum. On the *right lung* this part of the surface is depressed, and corresponds to the œsophagus; on the *left lung* it presents a broad longitudinal groove, which is produced by the contact of the lung with the thoracic aorta, and also, close to the base, a small flattened area ventral to this which is applied to the œsophagus immediately above the diaphragm.

The portion of the mediastinal surface of the lung which lies above the hilum and pericardial hollow is applied to the lateral aspect of the superior mediastinum, and the markings are accordingly somewhat different on the two sides. On the left lung a broad deep groove, produced by the aortic arch, curves dorsally above the hilum, and becomes continuous with the aortic groove on the dorsal part of the mediastinal surface. From the groove for the aortic arch a narrower, deeper, and much more sharply marked groove runs upwards, and laterally over the apex pulmonis a short distance from the summit. This is the **subclavian sulcus**, and it contains the left subclavian artery when the lung is in place. Ventral to the subclavian sulcus a shallow wide groove, also leading to the ventral aspect of the apex, corresponds to the left innominate vein. In the *right lung* the hilum is also circumscribed above by a curved groove, which is narrow and more distinctly curved than the aortic groove on the left side. It lodges the vena azygos as it turns ventrally to join the superior vena cava. From the ventral end of the azygos sulcus a wide shallow groove extends upward to the inferior part of the anterior aspect of the apex of the lung. This is produced by the apposition of the lung with the superior vena cava and the right innominate vein. Close to the summit of the apex there is also, on its medial aspect, a sulcus for the superior end of the innominate artery.

In addition to the hilum, it must now be evident that the mediastinal surface of each lung presents three areas which correspond respectively with (1) the middle mediastinum (*i.e.* the pericardial hollow), (2) the dorsal mediastinum, and (3) the superior mediastinum; and that in each of these districts impressions corresponding to structures contained within these portions of the interpleural space may be noticed.

The **dorsal part** of the lung at the junction of the costal and mediastinal surfaces is thick, long, and rounded. It forms the most bulky part of the organ, and occupies the deep hollow in the thoracic cavity which is placed at the side of the vertebral column.

The **ventral** or **anterior border** of the lung is short, and exceedingly thin and sharp. It begins abruptly immediately below the groove on the apex for the innominate vein, and extends to the base, where it becomes continuous with the sharp inferior border. The thin ventral part of the lung is carried ventrally and medially, ventral to the pericardium, into the narrow pleural costo-mediastinal sinus, dorsal to the sternum and costal cartilages. The ventral border of the right lung fills up this recess completely, and in the upper part of the chest is separated from the corresponding border of the left lung only by the two layers of mediastinal pleura which are reflected from the sternum to the pericardium. The ventral border of the left lung, in its lower part, shows a deficiency or notch, the **incisura cardiaca**, corresponding to the apex of the heart, and where this exists the lung margin leaves a considerable portion of the pericardium uncovered, and fails to fill up completely the costo-mediastinal sinus of the pleural cavity. During respiration the ventral margin of the left lung at the cardiac notch advances and retreats to a small extent in this pleural sinus, ventral to the pericardium.

Fissures and Lobes of the Lung.—The *left lung* is divided into two lobes by a long deep **interlobar fissure**, which penetrates its substance to within a short distance of the hilum. On the upper and lower sides of the hilum this fissure cuts right through the lung and appears on the mediastinal surface. Viewed from the costal surface, it begins dorsally about two and a half inches below the apex, about the level of the vertebral end of the third rib, and is continued downwards and ventrally in a somewhat spiral direction to the diaphragmatic surface of the lung, which it reaches a short distance from its ventral end. The **superior lobe** lies above and ventral to this cleft. It is conical in form, with an oblique base, and the apex and the whole of the ventral border of the lung belong to it. The **inferior lobe** lies below and dorsal to the fissure. It is the more bulky of the two, and includes almost the entire diaphragmatic surface and the greater part of the thick dorsal part of the lung.

In the *right lung* there are two interlobar fissures, which subdivide it into three lobes. One of these is very similar in its position and relations to the fissure in the left lung. It is directed, however, rather more vertically, and ends somewhat farther from the median plane. It separates the inferior lobe from the middle and superior lobes. The second interlobar fissure begins in the main fissure at the dorsal part of the lung, and proceeds ventrally, to end at the ventral border of the lung at the level of the fourth costal cartilage. The middle lobe of the right lung is triangular or wedge-shaped in outline.

Variations.—Variations in the pulmonary fissures are fairly common. Thus, it sometimes happens that the middle lobe of the right lung is imperfectly cut off from the superior lobe. Supernumerary fissures also are not infrequent, and in this way the left lung may be cut into three lobes, and the right lung into four or even more lobes. The occurrence of the **lobus azygos** in the right lung is a variation of some interest, seeing that such a lobe is constant in certain mammals. It is a small accessory lobe, pyramidal in form, which makes its appearance on the lower part of the mediastinal surface of the right lung. In certain cases the vena azygos is enclosed within a fold of pleura, and is sunk so deeply in the pulmonary substance of the right lung that it marks off a small accessory lobe.

RADIX PULMONIS.

The term **root of the lung** is applied to a number of structures which enter and leave the lung at the hilum on its mediastinal surface. They are held together by an investment of pleura, and constitute a pedicle which attaches the lung to the mediastinal wall of the pleural cavity. The phrenic nerve passes downwards a short distance ventral to the pulmonary root, whilst the vagus nerve breaks up into the dorsal or posterior pulmonary plexus on its dorsal aspect under cover of the investing pleura. The delicate ventral or anterior pulmonary plexus is placed ventral to the root of the lung under cover of the pleura, whilst from the inferior border of the root of the lung the ligamentum pulmonale extends towards the diaphragm. These relations are common to the pulmonary root on both sides of the body, but there are others which are peculiar to each side. On the *right side* the superior vena cava lies ventral to the pulmonary root, whilst the vena

azygos arches over its upper border. On the *left side* the aorta arches above the root of the lung, whilst the descending thoracic aorta passes dorsal to it.

Constituent Parts of the Pulmonary Root.—The large structures which enter into the formation of the pulmonary root are (1) the two pulmonary veins, (2) the pulmonary artery, (3) the bronchus. But in addition to these there are one or more small bronchial arteries and veins, the pulmonary nerves and the pulmonary lymph vessels, and some bronchial glands.

The **pulmonary nerves** come from the vagus nerve and also from the autonomic nervous system. They enter the lung and follow the air-tubes through the organ. The **bronchial arteries** are small vessels which carry blood for the supply of the lung-tissue. They arise from the aorta or from an intercostal artery, and vary in number from one to three for each lung. In the root of the lung they lie on the dorsal aspect of the bronchus, and they follow the air-tubes through the organ. Part of the blood conveyed to the lung by the bronchial arteries is returned by the pulmonary veins; the remainder is returned by special **bronchial veins** which open on the right side into the vena azygos, and on the left side into the vena hemiazygos.

The **lymph vessels** of the lungs are numerous and well developed, and are divided into two groups, superficial and deep.

The *superficial* lymph vessels form a network on the surface of the lung and eventually terminate by four or five vessels in the broncho-pulmonary glands of the hilum. It is usually stated that the superficial lymph vessels communicate freely with the deep. This, however, is denied by Miller, who maintains that anastomoses between the two systems of vessels are very rare. Free communication between the superficial and deep lymph vessels appears to occur only at the hilum of the lung.

The *deep* lymph vessels are subdivided into bronchial accompanying the bronchi, and vascular accompanying the blood-vessels. Both systems communicate freely together, and at the level of the hilum terminate in the broncho-pulmonary glands.

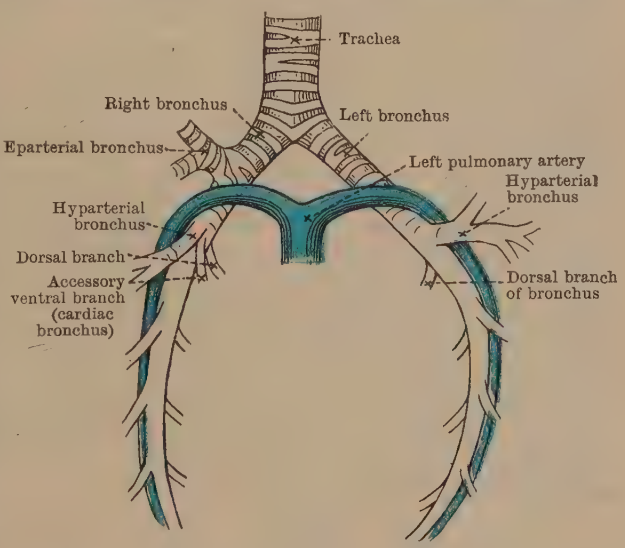

FIG. 848.—DIAGRAM OF THE RELATIONS OF THE PULMONARY ARTERY TO THE BRONCHI.

The pulmonary or broncho-pulmonary lymph-glands, found at the hilum, are usually numerous and variable in size. They are situated either just outside the lung or within the lung-substance itself.

From these broncho-pulmonary glands the lymph-flow is continued onward from the lung, partly directly into the thoracic duct, and partly by a more circuitous route as follows:—

From the broncho-pulmonary lymph-glands vessels pass on to the tracheo-bronchial glands situated at the angles produced by the bifurcation of the trachea into the two bronchi. Of these glands there are, therefore, three groups, an inferior and right and left superior. From these glands the lymph-flow is continued upwards through the tracheal lymph-glands lying on either side of the trachea into the deep cervical lymph-glands, and thence into the thoracic duct.

The **bronchus** in the root of the lung lies dorsal to the great pulmonary vessels. The **pulmonary artery** occupies a different position on the two sides, in relation to the main or undivided part of the bronchus. On the right side it is placed below it, whilst on the left side it crosses the bronchus and occupies a higher level in the pulmonary root. The two **pulmonary veins**, on both sides, lie at a lower level in the root of the lung than the pulmonary artery and bronchus, whilst the superior of the two veins occupies a plane ventral to the pulmonary artery (Figs. 846 and 847).

Distribution of the Bronchial Tubes within the Lungs.—The two lungs are not symmetrical; the right lung is subdivided into three lobes, and the left lung is cleft into two lobes. The bronchi exhibit a corresponding want of symmetry. The *right bronchus*, as it approaches the pulmonary hilum, gives off two branches for the superior and middle lobes of the right lung respectively, and then the main stem of the tube enters the inferior lobe. The *left bronchus* sends off a large branch to the superior lobe of the left lung, and then sinks into the inferior lobe. The first branch of the right bronchus, for the superior lobe, leaves the main

stem about one inch from the trachea. The first branch of the left bronchus, on the other hand, takes origin about twice that distance from the trachea.

The relation of the pulmonary artery to the bronchial subdivisions is different on the two sides. On the right side it turns dorsally, to reach the dorsal aspect of the bronchus, inferior to the first, and superior to the second, bronchial branch. On the left side the pulmonary artery turns dorsally above the level of the first bronchial branch. On the right side, therefore, the first bronchial branch is placed above the pulmonary artery, and in consequence it is termed the **eparterial bronchial ramus**; all the others lie below the artery, and are termed **hyparterial bronchial rami**. On the left side there is no eparterial branch; they are all hyparterial.

When the main stem of the bronchus is followed into the inferior lobe of each lung, it is seen to travel downwards and dorsally in the pulmonary substance until it reaches the thin dorsal part of the diaphragmatic surface of the lung which lies between the diaphragm and the thoracic wall, and there it ends. As it proceeds through the inferior lobe it gives off a series of large **ventral** and a series of smaller **dorsal branches**. As a rule these are three in number in each case, and the dorsal and ventral branches do not arise opposite to each other, but alternately, one from the dorsum, and then another, after a slight interval, from the ventral surface of the tube. The first hyparterial division on each side (*i.e.* the branch to the middle lobe of the right lung and the branch to the superior lobe of the left side) is generally regarded as the first member of the ventral group.

It was Aeby who first recognised the existence in each lung of a main or stem bronchus giving off a ventral and dorsal series of branches, and who drew the distinction between the eparterial and hyparterial bronchial rami. A consideration of these relations led this author to conclude that the eparterial bronchus and the superior lobe of the right lung have no morphological equivalents on the left side of the body. In other words, he was led to believe that the middle lobe of the right lung is the homologue of the superior lobe of the left lung. Hasse, who has also investigated the subject, endorsed this view, with certain modifications and additions; and the hypothesis, either in its original state as presented by Aeby, or as subsequently modified by Hasse, has been, until lately, very generally accepted by anatomists. More recent research, however, has seriously affected the stability of this conclusion. Narath contends that the distinction between the eparterial bronchus of the right side and the hyparterial bronchi of both sides is not one of fundamental importance, and that a branch which arises from the first hyparterial bronchus on the left side and turns upwards into the apex of the left lung is the direct equivalent of the eparterial bronchus of the right side. This he terms the **apical bronchus**, and he believes that it represents the first dorsal branch of the left stem-bronchus. Huntington, in a very convincing paper, strongly supports the contention of Narath, and holds that, except "for purposes of topography, we should abandon the distinction between eparterial and hyparterial bronchi." With Narath he regards the eparterial bronchus as a secondary branch which has migrated in an upward direction on the main stem. According to Huntington, therefore, Aeby's proposition should be amended as follows:—

Right side.				Left side.
Superior	and	middle lobes	=	Superior lobe.
Inferior	and	cardiac lobes	=	Inferior lobe.

The cardiac lobe mentioned in this table is the occasional azygos lobe to which reference has already been made, and it is interesting to note that, whilst the lobe in question as a separate entity is rarely seen in the human lung, the bronchus which corresponds to it is always present in the pulmonary substance as an accessory branch, which proceeds from the main stem as it traverses the inferior lobe of the right side. It receives the name of the **cardiac bronchus**.

Structure of the Lung.

The lung is constructed so that the blood which reaches it through the pulmonary artery is brought into the most intimate relation with the air which enters it through the trachea and bronchi. An interchange of materials between the blood and the air is thus rendered possible, and the object of respiration is attained. As a result of this interchange the dark, impure blood, which flows into the lung through the pulmonary artery, is rendered bright red and arterial.

Lobules of the Lung.—A thin layer of subpleural connective tissues lies subjacent to the continuous coating which the lung receives from the pulmonary pleura. From the deep surface of this subpleural layer fine septal processes penetrate into the substance of the lung, and those, with the connective tissue which enters at the hilum upon the vessels and bronchi, constitute a supporting framework for the organ. The lung is lobular, and on the surface the small polygonal areas which represent the lobules are indicated by the pigment present in the connective tissue septa which intervene between them. Although no pigment is present, the lobular character of the lung is particularly well marked in the fœtus, and with a little care the surface lobules in the fœtal lung can be separated from each other by gently tearing through the intervening connective tissue. The lobules thus isolated are piriform or pyramidal in form. The broad bases of these lobules abut against the subpleural layer, whilst each of the deep narrow ends receives a minute division from the bronchial system of tubes. The lobules which lie more deeply in the substance of the organ are not so large, and are irregularly polygonal in form.

The Lung-Unit. The unit of lung-structure is the lung-lobule. This comprises a terminal bronchus with its air-spaces, blood-vessels, lymph vessels, and nerves.

The terminal bronchus of the lung-unit is attained as follows:—The larger branches of the bronchi, as they traverse the lung, give off numerous divisions, which, by repeated branching,

ultimately form a system of tubes which pervade the entire organ. At first the bronchial divisions come off at very acute angles, but as the finer ramifications are reached this character becomes much less apparent. The finer ramifications of the bronchi are termed *bronchioles*, which by subdivision give rise to the *respiratory bronchiole* of the lung-unit.

Within the lung-unit the respiratory bronchiole gives off a series of terminal bronchi or *alveolar ducts*, each of which leads to a group of air-spaces termed *atria*. Each one of the atria communicates, in its turn, with a further and secondary series of air-spaces termed air-sacs or *alveolar saccules*, the walls of which are pouched out to form the very numerous *alveoli* or *air-cells* of the lung-unit.

Structure of the Bronchi.—When the large bronchi enter the lung they become cylindrical, and lose the flattening on the dorsal aspect which is characteristic of the primary bronchi outside the lung. They possess the same coats as are present in the case of the trachea and primary bronchi, but as the tubes become smaller by repeated divisions, these coats become correspondingly thinner and finer. Certain differences also in the manner in which the constituents of these coats are arranged become apparent.

In the **external fibro-cartilaginous coat** the cartilage is no longer present in the form of incomplete rings, but in irregular plates or flakes deposited at various points around the wall. As the tubes diminish, the cartilaginous deposits show a corresponding reduction in size, until at last, in bronchi of 1 mm. diameter, they disappear altogether. The **glands** in relation to the tubes for the most part cease to exist about the same point. The **muscular** or **middle coat**, which in the trachea and primary bronchi is confined to the dorsal wall of the tube, forms a continuous layer of circularly arranged bundles in the bronchi as they ramify within the lung. Spasmodic contraction of the muscular coat gives rise to the serious symptoms which accompany asthmatic affections. The muscular fibres of the middle coat may be traced as far as the atria, on the walls of which they are present in considerable numbers. The **mucous lining** of the tubes becomes greatly thinned as it is followed into the smaller bronchioles. It contains a large number of longitudinally arranged elastic fibres, and is disposed in longitudinal folds, so that when the tube is cut across the lumen presents a stellate appearance. The mucous membrane is lined with ciliated columnar epithelium.

Structure of the Atria and Alveoli.—The walls of the atria and alveoli are exceedingly fine and delicate, but, nevertheless, constituents continuous with those observed in the three coats of a bronchus are found entering into their construction. The epithelium is reduced to a single layer of non-nucleated cells. Further, it is no longer columnar and ciliated, but it has become flat and pavement-like. Two kinds of epithelial cells may be recognised—(1) a few small granular polygonal cells, arranged singly or in groups of two or three, (2) more numerous thin cells of large size and somewhat irregular in outline. Outside the epithelium is a delicate layer of faintly fibrillated connective tissue. This is strengthened by a network of elastic fibres, which is specially well marked around the mouths of the alveoli, and is also to some extent carried over the walls of the air-cells. Muscular fibres also are present on the walls of the atria, but it is questionable if any are prolonged over the air-cells.

Pulmonary Vessels.—The pulmonary artery, as it traverses the lung, divides with the bronchi, and closely accompanies these tubes. The resultant branches do not anastomose, and for the most part they lie above and dorsal to the corresponding bronchi. The fine terminal divisions of the artery join a dense capillary plexus which is spread over the alveoli or air-cells. This vascular network is so close that the meshes are barely wider than the capillaries which form them. In the partition between adjacent alveoli there is only one layer of the capillary network, and thus the blood flowing through these vessels is exposed on both aspects to the action of the air in the air-cells. The radicles of the pulmonary vein arise in, and carry the blood from, the pulmonary capillary plexus. Each afferent arteriole supplies the blood which flows through the capillaries spread over a number of neighbouring alveoli, and in like manner each afferent venous radicle drains an area corresponding to several adjoining air-cells. At first the veins run apart from the arteries, but after they have attained a certain size they join them and the bronchi. As a rule the pulmonary veins are placed on the inferior and ventral aspects of the corresponding bronchi.

X-Ray Appearances of the Chief Thoracic Viscera.—A knowledge of the normal and morbid appearances of the chief thoracic viscera, as seen with X-rays, is of clinical importance. The following account of these appearances is based chiefly on Dr. J. Stuart Dickey's work on the subject.

In health the **lungs** should appear clear, especially during inspiration, and in emphysema will be almost abnormally clear, because the greater the amount of contained air the more permeable does the thorax become to the passage of the X-rays, and the less the shadow cast. On the other hand, organs which contain much blood, such as the liver, heart, and blood-vessels, tend to cast a shadow. It consequently follows that diseases of the lung which are characterised by increased vascular engorgement tend to diminish the permeability of the lung to the passage of the rays, and to throw a shadow. In congestion and œdema of the lungs there is, therefore, a diminished transradiance, as there also is in collapse of the lung. In lobar pneumonia the density of the lung is uniformly increased, whilst in broncho-pneumonia there is a scattered dark mottling of the lung. In such localised affections of the lung as occur in tumours, infarcts, cysts, abscesses, and cirrhosis, there are found localised areas casting a denser shadow.

The **bronchi** can occasionally be seen with the X-rays as faint areas of increased density, especially when expansion of the lung is restricted by consolidation or when the breathing is unusually quiet.

Bronchial lymph-glands are rarely visible unless they are enlarged or tubercular. They usually appear as separate, dark, mottled areas to the right of the cardiac shadow.

As regards the **pleura** it is naturally only visible with the X-rays when diseased. In thickened pleura there may be an increased density which is not affected by position or by tapping. Pleural effusion also gives an increased density of shadow with a blurring of the cardio-hepatic angle and the outline of the diaphragm.

Enlargement of the heart, pericardial effusion, mediastinal tumour, aneurysm of the aorta, etc., all give rise to X-ray areas of increased density, and by leading to compression of the lung may diminish its normal transradiance. Rotch emphasises the importance of the cardio-hepatic angle as a means of diagnosing pericardial effusion from enlargement of the heart. In the latter case the angle is about 90° and is obliterated in pericardial effusion.

Foreign bodies in the bronchi, lungs, or pleural cavities are, of course, often located by means of the X-rays.

Development of the Respiratory Apparatus.

The larynx, trachea, bronchi, and lungs all arise as an outgrowth from the ventral aspect of the foregut. The first indication of a respiratory tract occurs in the human embryo early in the third week, on or about the fifteenth day of development, and when the embryo is but little more than 3 mm. in length. At that period a median longitudinal groove makes its appearance in the ventral wall of the foregut, extending from the primitive pharynx well towards the primitive stomach, and deepening gradually as it passes caudalwards.

The cranial end of the respiratory tube becomes enlarged and forms the larynx, the intermediate portion forms the trachea, and the caudal end bifurcates in the floor of the groove into two tubes—the future bronchi are already indicated by slight bulgings before the two tubes divide—which grow caudalwards on either side of the heart, into a mesodermic mass, from which the connective tissue of the future lungs is ultimately developed. The respiratory tube is lined with entoderm continuous with the entodermal lining of the foregut.

The groove becomes deeper and constricted, its lateral margins approximate, and finally meet dorsally, and the groove separates off from the foregut as a distinct tube. This differentiation necessarily results in the production of two tubes or canals, a ventral one forming the respiratory tube, and a dorsal one the œsophagus. The separation of the two tubes commences at the caudal end and proceeds cranialwards towards the pharynx, into which both the œsophagus and the respiratory tube open.

The Larynx.—The rudiment of the larynx appears, at the cranial or pharyngeal end of the primitive respiratory tube, about the twenty-fifth day, and before the trachea separates off from the œsophagus in the form of two lateral swellings—the arytænoid swellings, which lie caudal to the fourth visceral pouches, and possibly represent rudimentary fifth branchial arches (Kallius). The arytænoid swellings are connected by a ventral median ridge which intervenes between the ventral ends of the third visceral arches. At this period the site of the future larynx is represented at the pharyngeal end of the respiratory tube by a U-shaped ridge which surrounds the tube cranially and laterally, and is known as the *furcula*.

The cranial or anterior portion of the furcula forms a median elevation from which the epiglottis is developed, whilst the lateral portions of the furcula—the arytænoid swellings—eventually form the ary-epiglottic folds. On the medial side of the latter, about the fourth month, a furrow marks the future site of the ventriculus laryngis [Morgagni], the margins of which later become the vocal folds.

About the eighth week the cartilaginous framework of the larynx is indicated by mesoblastic condensations of the connective tissue around the now slit-like rima glottidis ; and at the same period the rudimentary arytænoids, the cricoid, and the cartilages of the trachea are all continuous laterally.

The *epiglottic cartilage* is developed, as stated, in the anterior portion of the furcula, and chondrifies relatively late. It may possibly represent a rudiment of the cartilage of the sixth branchial arch, and according to Göppert it is at first continuous dorsally with the cuneiform cartilages, which, therefore, are derivatives of the epiglottic cartilage.

The *thyreoid cartilage* is laid down in the form of two separate lateral mesoblastic plates, in each of which chondrification proceeds from two centres, ventral and dorsal, which probably represent the cartilages of the fourth and fifth branchial arches. As development proceeds the sheets of cartilage formed from these centres fuse, and eventually extend ventrally to fuse with their fellows of the opposite side, in the median plane. Chondrification is completed comparatively late, and when incomplete it results in the formation of an abnormality—the thyreoid foramen. The superior cornu of the thyreoid cartilage is at first continuous with the greater cornu of the os hyoideum, and the remains of this cartilaginous connexion is seen in the presence of the cartilago triticea in the lateral hyothyreoid ligament of the adult.

The pro-cartilaginous rudiments of the cricoid and arytænoid cartilages are at first continuous with each other, but later become differentiated by the appearance of separate cartilaginous centres for the arytænoids, and an incomplete ring, for a time deficient dorsally, for the cricoid. The cricoid thus resembles developmentally a tracheal ring, with which it probably corresponds morphologically. Chondrification proceeds in the cricoid by two centres, one on each lateral side. These centres unite ventrally, but dorsally fusion does not take place until much later, and is finally completed by an extension of chondrification from the lateral into the dorsal plate. The cricoid thus differs from the tracheal ring, in having its chondrification completed dorsally, whereas this never takes place in the tracheal ring.

The *arytænoid cartilages* are, as stated, at first continuous with the cricoid cartilage by fibrous tissue, but become eventually completely separated from it by the appearance of one chrondrification centre for each arytænoid.

The *corniculate cartilages* (*Santorini*) are merely portions of the arytænoid cartilages separated off by segmentation; whilst the *cuneiform cartilages* (*Wrisbergi*) are, as previously stated, derivatives of the epiglottic cartilage.

The Trachea.—The trachea is developed from the intermediate portion of the median longitudinal groove. Originally, both this portion of the primitive respiratory tube and the œsophageal portion of the primitive alimentary canal were of equal length; but as development proceeds both tubes lengthen, the latter more rapidly than the former, so that eventually the lung rudiments no longer lie on the ventral and lateral sides of the primitive stomach, but come to lie on the cephalic side of that viscus, and are separated from each other by the œsophagus dorsally and the heart and pericardium ventrally. In this way, that is by unequal growth, it comes about that the trachea in the adult is shorter than the œsophagus, though originally both were of equal length.

The cartilaginous rings of the trachea are developed like the cricoid cartilage, with the difference that in the trachea the process of chondrification does not extend into their dorsal portions, and hence, in the adult, the C-shaped rings of the trachea are deficient dorsally—an arrangement which admirably adapts itself to the functional uses of both trachea and œsophagus.

The Lungs.—The lungs are developed from the two diverticula of the caudal end of the median longitudinal groove and the mesodermal tissue into which these grow. Originally single, this caudal end soon becomes bilobed and pouches out on each side into two lateral diverticula, which represent the primitive bronchi and lungs. From the first the right pulmonary diverticulum or vesicle is slightly the larger of the two. Both diverticula elongate, and almost immediately undergo a subdivision—the right into three vesicles, and the left into two vesicles—thus early indicating the three lobes of the right lung and the two lobes of the left lung. As the primitive respiratory tube lies in the median plane in the dorsal attachment of the septum transversum, the pulmonary diverticula grow laterally and dorsally into the dorsal parietal recesses, that is into the future pleural cavities, carrying before them a covering of mesoblast. From this mesoblast are derived the blood-vessels and other tissues which build up the lung, whilst the entodermal cells which form the lining membrane of the primitive respiratory tube eventually develop into the epithelial lining of the air-passages, and are embedded within the surrounding mesoderm. The main entodermal subdivisions continue to branch and re-branch, pushing their way into the pulmonary mesoblast, until the complete bronchial tree is formed.

The primary pulmonary diverticula increase in size and complexity as additional outgrowths arise by the subdivision of the enlarged terminal part of each diverticulum. Their mode of subdivision is very characteristic, and from the first the various branches are bulbous or flask-shaped at their extremities. These bifurcate, and although at first the two main subdivisions appear, in each case, of equal importance, one grows out as the continuation of the main bronchial stem—the future hyparterial bronchus—whilst the other remains as a branch. This budding of the developing lung is at first monopodial, but later probably becomes dichotomous. When the ramification of the entodermal tubes into the lung-mesoderm is complete, the small terminal flask-shaped extremities of the various branches represent the atria of the lung.

This repeated bifurcation results, as just stated, in the formation of a main bronchus which traverses the entire length of the lung, and into which numerous secondary bronchi open. The latter, from the manner in which they arrange themselves around the main stem of the pulmonary artery, are divided into dorsal and ventral. These alternate with each other, and usually number four in each series; not infrequently the third dorsal bronchus fails to develop. In the left lung the first dorsal bronchus arises, not from the main tube as on the right side, but from the first ventral bronchus—an arrangement which probably results from the fusion on the left side of the superior and middle lobes of the left lung into one, namely, the so-called lobus superior of the adult left lung.

The secondary bronchi elongate, and give rise to the tertiary bronchi, and these in turn to lesser bronchi, and so on down to the terminal bronchi, with their atria, air-sacs, and air-cells of the lung-unit. At first the lung-unit is devoid of air-cells, but between the sixth month and full term the alveolar saccules and air-cells make their appearance on the alveolar ducts; and it is thus clear that the epithelial lining of the entire system of bronchial subdivisions and ramifications is derived originally from the entodermal lining of the primitive foregut. By the close of the fourth month of fœtal life the columnar cells lining the trachea and bronchi have become ciliated.

At first the diverticula of the respiratory tube are surrounded by thick masses of mesoblastic tissue, but as development proceeds the latter fails to keep pace with the former, and hence the mesoblastic tissue becomes greatly reduced in amount and in thickness. Coincidently, this mesoblast becomes vascularised, and thus rich plexuses of blood-vessels come to surround the terminal divisions of the epithelial tubes—an arrangement obviously adapted to the interchange of gases from air to blood and *vice versa*.

The rudiments of the developing lungs grow dorsally on each side of the œsophagus into the fissure-like portion of the cœlom which occupies the thoracic region. They push before them the endothelial lining of the cœlom, and thus come to acquire their covering of pulmonary pleura. By the development of the diaphragm and the pericardium the pleural portions of the cœlom become cut off from the peritoneal cavity and from each other.

THE DIGESTIVE SYSTEM.

David Waterston, M.A., M.D., F.R.C.S.E.,

Bute Professor of Anatomy in the University of St. Andrews.

APPARATUS DIGESTORIUS.

The Digestive System.—The physical characters and the chemical composition of the food taken into the body are such that much of it cannot at once be utilised by the organism. Before it can be absorbed and used in nutrition it requires to be acted upon, both chemically and mechanically. The performance of these mechanical and chemical changes is known as *digestion.*

The term **apparatus digestorius** (digestive system) is applied collectively to the organs which are concerned in this process, in the reception of food into the body, and in the excretion of the undigested or unabsorbed residue.

The simple form of digestive system which is found in many of the lower animals consists of a simple tube, passing through the interior of the body, from an anterior or mouth aperture, to a posterior or anal orifice.

In man, a tube of this kind forms the basis of the digestive system. It extends from the mouth, through the neck, thorax, abdomen, and pelvis, to the anal orifice and is termed the alimentary canal. The tube, originally simple, has become modified, in different directions in different parts, for the performance of the various processes. The wall and lining membrane are so constructed as to be capable of acting mechanically and chemically upon the food in its interior, of absorbing and transmitting products of digestion into the adjacent blood and lymph vessels, and of ejecting the unabsorbed remains.

Alimentary Canal.—The alimentary canal, taken as a whole, measures, when fully extended, about 30 feet (9 metres) in length, and consists of the following parts in order:—mouth, pharynx, œsophagus, stomach, small and large intestines. The term **tubus digestorius** is applied to the whole of the canal below the lower end of the pharynx. The general arrangement, position, and size of these various parts are shown in the figure (Fig. 849).

CAVUM ORIS.

The **mouth** forms the first division of the alimentary canal. It lies between the maxillæ and mandible, bounded externally by the lips and the cheeks, and roofed in by the palate. It contains the teeth and greater part of the tongue; and the ducts of the salivary glands open into it. It communicates with the exterior by the aperture of the mouth, and opens posteriorly into the pharynx.

Rima Oris.—The **aperture of the mouth** is bounded above and below by the corresponding lips, which meet at the sides and form the **commissures** of the lips, and bound the angles of the mouth (anguli oris). In a state of rest, with the lips in apposition, the rima forms a slightly curved line, corresponding in length to

the interval between the first premolar teeth, and in level to a transverse line just below the middle of the upper incisor crowns. The shape of the rima varies with every movement of the lips, from the resting linear form, curved like

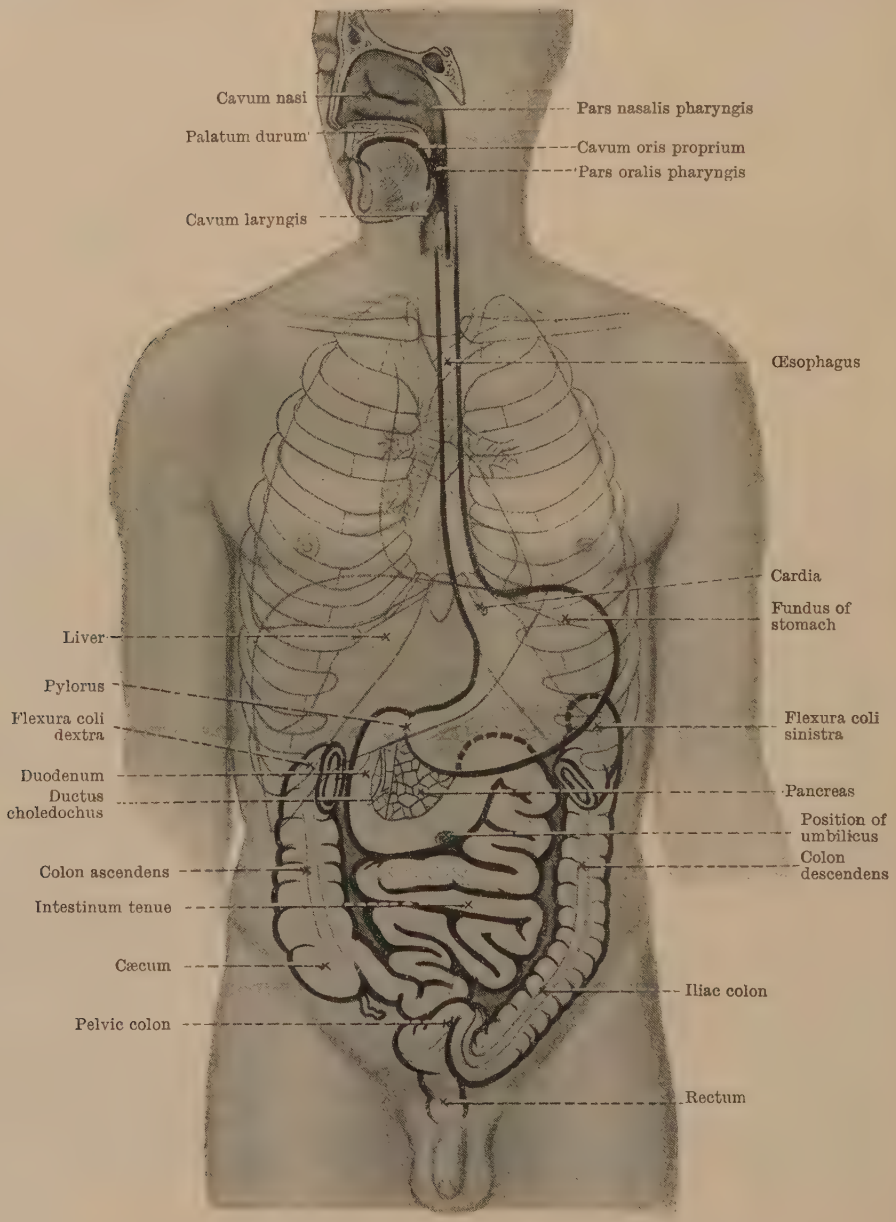

FIG. 849.—DIAGRAM OF THE GENERAL ARRANGEMENT OF THE DIGESTIVE SYSTEM.

The transverse colon is not represented, in order that the duodenum and pancreas, which lie behind it, may be seen.

the conventional bow, to a circular or oval shape when the mouth is widely open, or the "pursed-up" condition produced by the contraction of the orbicularis oris muscle.

The cavity is divisible into two portions, the *vestibule* and the *cavity proper* of the mouth, separated from one another by the alveolar ridges, gums, and teeth of the maxillæ and mandible.

Vestibulum Oris.—The **vestibule of the mouth** lies immediately internal to the

aperture of the mouth, and occupies the interval between the lips and cheeks externally, and the teeth and gums internally.

In the normal resting condition, when the mouth is closed and the lips and the teeth are in contact, it becomes merely a slit-like interval, with a narrow roof and floor formed by the reflexion of the mucous membrane from the internal surface of the lips and cheeks to the corresponding gum. In the median plane is a small but prominent fold of the mucous membrane, the **frenulum**, which connects the back of each lip to the front of the gum. The upper frenulum is the better developed, and is readily brought into view by everting the lip. The frenulum of the lower lip is not always present.

On the outer wall of the vestibule, opposite the crown of the second upper molar, is a variably developed eminence, on whose summit is the small opening of the duct of the parotid gland.

When the teeth are in contact the vestibule communicates with the cavity of the mouth only through the small and irregular spaces left between the opposing teeth, and posteriorly, on either side, by a wider but variable aperture between the last molars and the ramus of the mandible.

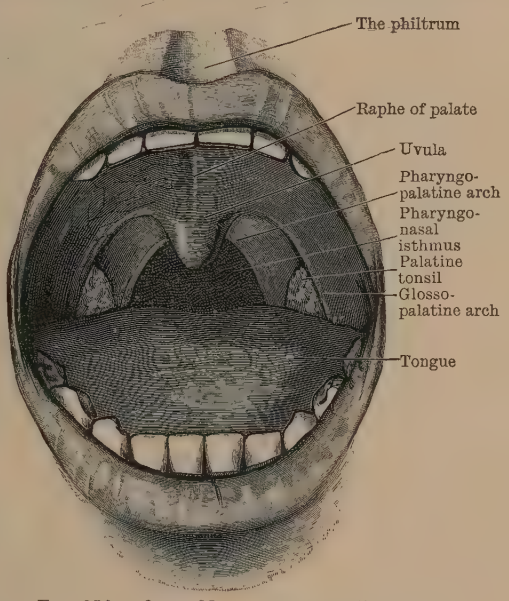

FIG. 850.—OPEN MOUTH SHOWING PALATE AND PALATINE TONSILS.

It also shows the two palatine arches, and the pharyngo-nasal isthmus, through which the naso-pharynx, above, communicates with the oral portion of the pharynx, below.

Advantage is sometimes taken of the presence of this aperture for the introduction into the cavity of the mouth of liquid food in certain cases—trismus, anchylosis, etc.—in which the jaws are rigidly closed.

On the outer wall of the vestibule, the anterior border of the masseter can be distinctly felt with the finger, when the muscle is thrown into a state of contraction. Still further back, the front of the coronoid process, bearing the lower part of the insertion of the temporal muscle, can also be made out. The spheno-mandibular ligament, which corresponds to, and is felt along with, the anterior border of the internal pterygoid muscle, is distinguishable as a pliant ridge when the finger is carried from the front of the coronoid process behind the last molar tooth into the cavity of the mouth.

In addition to the duct of the parotid, the ducts of numerous small glands which are embedded in the lips and cheeks open into the vestibule.

Under normal conditions, as pointed out above, the lips and cheeks lie against the teeth and gums, obliterating the cavity of the vestibule, and helping, with the aid of the tongue, to keep the food between the grinding surfaces of the molar teeth during mastication. In facial palsy, however, owing to the paralysis of their muscles, and particularly of the buccinator muscle, the lips and cheeks fall away from the dental arches, and allow the food to pass out from between the teeth and to accumulate in the vestibule.

Cavum Oris Proprium.—The **cavity proper of the mouth** is the space situated within the arches of the teeth and gums, extending backwards to the glosso-palatine arches (O.T. anterior pillars of the fauces)—two folds of mucous membrane which pass from the palate to the side of the tongue, and mark the junction of the mouth and the pharynx. The roof is formed by the **hard palate** and the anterior portion of the **soft palate**, the floor by the anterior part of the tongue in the middle, and on each side by the reflexion of the mucous membrane from the side of the tongue to the gums.

If the tongue is raised, there is exposed a limited space termed the sublingual space (Fig. 867), or floor of the mouth.

The term "floor of the mouth" is frequently applied to the muscular and other structures, especially the mylo-hyoid muscles, which fill in the interval between the two halves of the body of the mandible, and, with the hyoid bone, form the basis upon which the tongue and the

mucous membrane of the sublingual space are supported, extending from the symphysis menti, in front, to the body of the hyoid bone, behind.

The floor of the sublingual region (Fig. 867) is formed by the mucous membrane between the gums and the inferior aspect of the tongue. When the tip of the tongue is raised the membrane forms in the median plane a prominent fold, the **frenulum linguæ**, stretching from the floor of the mouth to the inferior surface of the tongue. On each side of the frenulum, near its junction with the floor, is a prominent soft papilla, the **caruncula sublingualis**, on which opens the **duct**

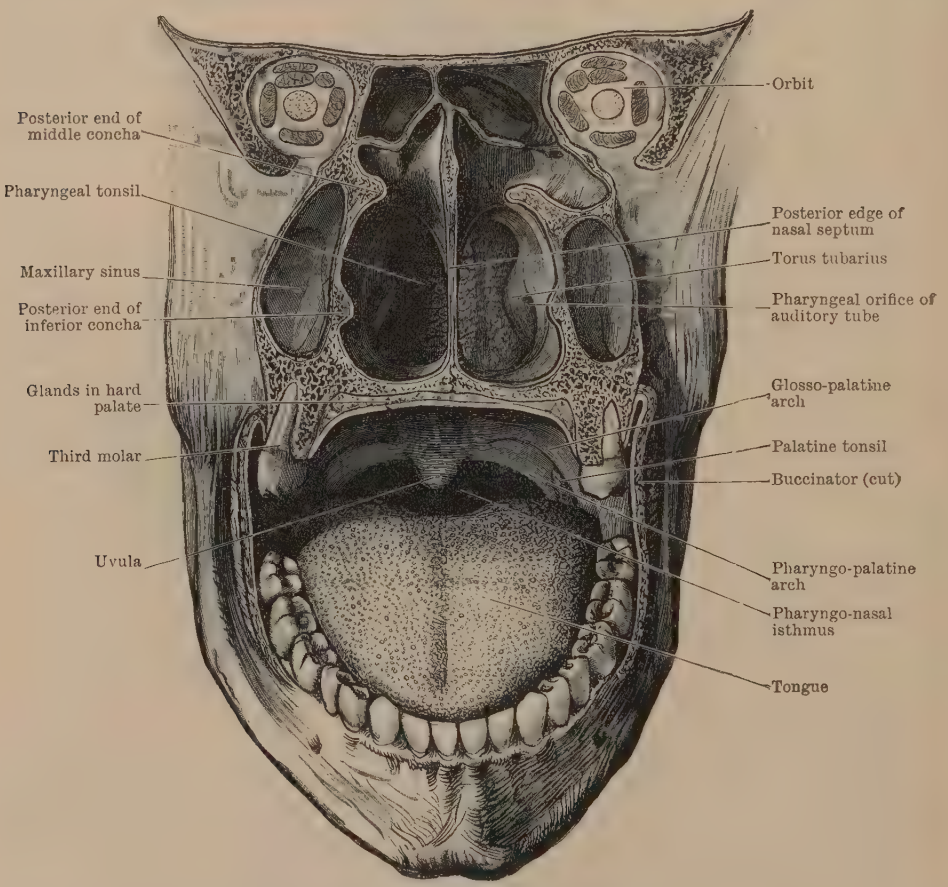

FIG. 851.—THE MOUTH AND THE NASAL PART OF THE PHARYNX FROM THE FRONT.

A frontal section was made through the upper part of the head; the section passed immediately in front of the posterior edge of the nasal septum, and extended into the mouth below. Through the choanæ, the nasal part of the pharynx is seen. The prominence of the posterior margin of the ostium pharyngeum of the auditory tube, and the lymph nodules constituting the pharyngeal tonsil, should be noted. The palatine arches and tonsils, and an unusually wide pharyngo-nasal isthmus, are also seen.

of the submaxillary gland (Fig. 867). Running laterally and posteriorly, on each side, from the frenulum, is a well-marked ridge, **plica sublingualis**, due to the projection of the underlying sublingual gland. Most of the ducts of this gland open near the crest of the ridge on each side. Another fold, called the **plica fimbriata**, lies medial to each of the others, on the inferior surface of the tongue.

This fold represents the under-tongue of some mammals, in whom it is a sort of fringe, stated to be of service in cleaning the incisor teeth (F. W. Jones).

Labia Oris.—The **lips** are the two mobile folds, covered superficially by skin, and on their deep surface by mucous membrane, which surround the rima oris. Laterally, they are prolonged into the cheeks, and below into the chin. The junction of the lips and cheek is marked on the surface by the **sulcus naso-labialis**,

a slight groove which passes downwards and laterally from the margin of the nose towards the angle of the mouth, while the **sulcus mento-labialis** separates the lower lip from the chin. At the middle of the upper lip is a shallow vertical groove, the **philtrum**, bounded by two distinct ridges descending from the columella nasi (Fig. 852); inferiorly the groove widens out, and terminates opposite a slight projection on the free edge—the *labial tubercle*. This tubercle is particularly well developed in children, and is chiefly responsible for the characteristic curve of the rima oris. The lower lip is usually longer and more movable than the upper lip.

For the manner in which the various muscles enter into the formation of the lip, see section on the Muscles (pp. 450-453).

In each lip the following series of structures can be recognised from the external to the internal surface:—(1) The **skin**, which is closely beset with hairs, small and fine in the child and female, long and stout in the adult male. (2) A layer of fatty **superficial fascia** continuous with the fascia of the face generally. (3) The **orbicularis oris muscle**, continuous at its periphery with the various muscles converging towards the mouth. A number of its fibres, or those of the muscles joining it, pass through the superficial fascia and are attached to the skin. (4) The **submucous tissue**, which is occupied by an almost continuous layer of racemose glands—the **labial glands**. These form a mass of small nodular glands, each about the size of a grape seed, closely packed together, and lying immediately external to the mucous membrane of the upper and lower lips. Each nodule is a small racemose gland, lined by mucous secretory cells, with a short duct opening through the mucous membrane. (5) The **mucous membrane** of the mouth, covered by stratified squamous epithelium. Between the orbicularis and mucous membrane, in the deeper part of the submucosa, the labial artery is found, a short distance from the free margin of the lip, running to meet its fellow of the opposite side.

FIG. 852.—OPEN MOUTH WITH TONGUE RAISED, AND THE SUBLINGUAL AND ANTERIOR GLANDS EXPOSED.

The sublingual gland of the left side has been laid bare by the removal of the mucous membrane; to expose the anterior lingual gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the medial aspect of the gland. The profunda vein also is faintly indicated on this side.

The free margin of the lip is covered with a dry and otherwise modified mucous membrane. It begins where the integument changes colour at the outer edge of the lip, and ends posteriorly just behind the line along which the two lips meet when closed, where it passes into the ordinary moist mucous membrane of the vestibule. It presents numerous simple vascular papillæ, and its nerves terminate in special end organs, hence the acute sensitiveness of this part. In the child, at birth, the margin of the lip is divided by a very pronounced groove or fissure into an outer and an inner zone, differing considerably in their appearance.

Blood-vessels, Nerves, and Lymph-vessels.—The lips receive a free blood supply, the lower lip from the inferior labial, and the upper from the superior labial branches of the *external maxillary artery*.

The sensory nerve supply of the lips is derived from the **trigeminal nerve**, that of the upper through the *infra-orbital branch* of the maxillary division, and that of the lower from the *mental branch* of the inferior alveolar branch of the mandibular division, while the **buccinator** branch of the mandibular division supplies the region of the angle. The lymph-vessels of the upper lip pass with the external maxillary artery to the **submaxillary lymph-glands** lying in the sub-

maxillary triangle, while those from the lower lip pass in part to the same glands, and in part to the *submental glands* lying on the mylo-hyoid muscles, above the hyoid bone.

Buccæ.—The **cheeks** resemble the lips in structure, and are formed of corresponding layers, but the place of the orbicularis oris muscle is taken by the buccinator muscle. They are covered externally by the skin and internally by the mucous membrane. Under the skin lies the fatty superficial fascia of the face, much looser in texture than in the lips, through which the **parotid duct** (of Stensen) runs inwards to pierce the buccinator. Near the end of the duct are found four or five mucous glands, as large as hemp-seeds, known as the **molar glands**; their ducts pierce the cheek and open into the vestibule. Beneath the superficial fascia lies the *buccinator muscle*, covered by the thin bucco-pharyngeal fascia. Deeper still is the submucosa, which, like that of the lips, contains numerous racemose **buccal glands**. And finally the mucous membrane is reached.

The **corpus adiposum buccæ** (O.T. **sucking pad**) is an encapsuled mass of fat, distinct from the surrounding superficial fascia, which lies on the outer side of the buccinator, and passes backwards into the large recess between that muscle and the overlying part of the masseter. This fatty mass is relatively more developed in the child than in the adult, and strengthens the cheek

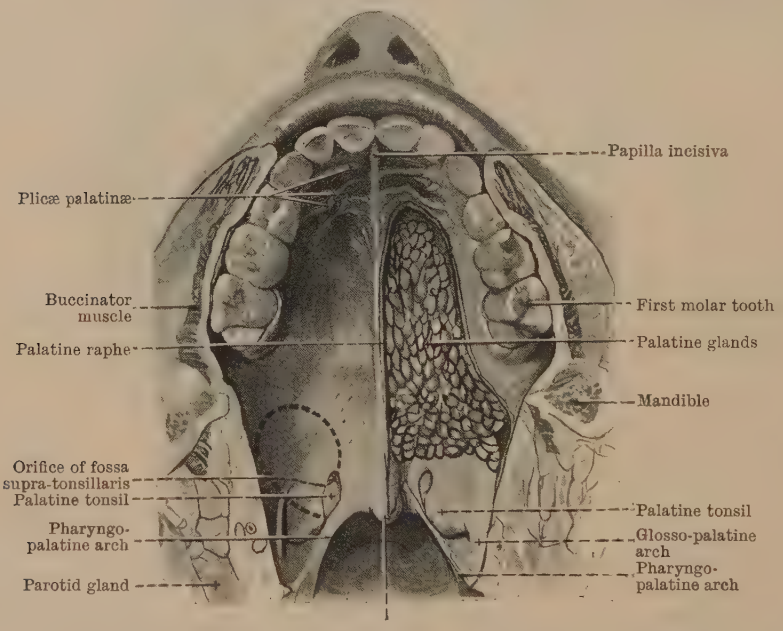

FIG. 853.—PALATE FROM BELOW. The mucous membrane has been removed over an area on the left side. From a child of ten years. The glosso-palatine arch was largely adherent to the anterior surface of the tonsil, and its free margin was thus obscured. The dotted line shows the extent of the supra-tonsillar fossa.

to resist the effects of atmospheric pressure during the act of sucking. In the adult the remains of the pad can be distinctly made out under the anterior border of the masseter.

Some small superficial lymph-glands lie on the superficial surface of the buccinator, communicating with the vessels of the lips, while their efferent vessels pass onwards towards the parotid region.

Palatum.—The **palate** forms the roof of the mouth, and separates the mouth from the nasal cavities and nasal part of the pharynx. From the mouth it extends backwards into the cavity of the pharynx, forming the division between the oral and the nasal parts of the pharynx. It terminates behind in a free conical projection, the **uvula**.

It consists of two portions, an anterior, forming the anterior two-thirds, which has a bony foundation, and a posterior, forming the posterior third, with a fibrous basis; and they are termed the hard and the soft palate respectively. The palate is arched antero-posteriorly, and also transversely. The latter curvature is the

more pronounced in the hard palate, but the shape and curvature of this portion depend upon the configuration of its bony foundation.

The hard palate is, on the whole, horizontal in direction, both transversely and antero-posteriorly. The soft palate is, on the other hand, during rest, as, for instance, in quiet nasal breathing, very oblique in direction, and it shuts off the mouth from the nasal and largely from the oral parts of the pharynx. When, however, the soft palate is raised, as in swallowing, it continues backwards the plane of the hard palate, and projects across the cavity of the pharynx, forming a nearly complete partition between the oral and the nasal parts of the pharynx. In this position it prevents food from passing upwards into the nasal part of the pharynx and nose.

Along the middle of the palate is a faint median ridge or **raphe** (Fig. 853), indicating its original development from two halves. This raphe is continued posteriorly along the soft palate to the base of the uvula, and in front it ends in a slight elevation, the **papilla incisiva**. From the anterior end of the raphe a series of transverse ridges of mucous membrane, about six in number, run laterally, just behind the incisor teeth; they are known as the **plicæ palatinæ**, and are composed of dense fibrous tissue. Sometimes a small pit, which will admit the point of a pin, is seen, on each side, immediately posterior to the central incisor teeth, and about 2 mm. from the median plane. These pits correspond to the inferior openings of the incisive canals, with which they are occasionally continuous.

Palatum Durum.—The **hard palate** consists of a horizontal plate formed by the palatine processes of the maxillæ and the horizontal parts of the palatine bones, covered on each surface, superior and inferior, by periosteum. The periosteum of the inferior surface is thick, and is in turn covered by a quantity of dense fibrous tissue firmly united both to the periosteum and to the mucous membrane. This dense tissue contains in its posterior half a large number of racemose palatine glands, and it also contains the larger nerves and blood-vessels of the palate. The mucous membrane covering the superior surface is largely ciliated in character, and forms the floor of the nasal cavity, while that on the inferior surface is a stratified squamous epithelium.

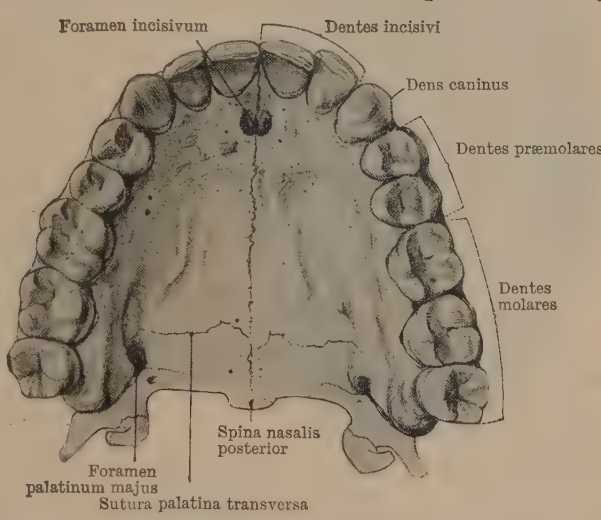

FIG. 854.—THE HARD PALATE AND UPPER PERMANENT TEETH, SEEN FROM BELOW.

Palatum Molle.—The **soft palate** is attached anteriorly to the posterior margin of the hard palate. Its lower and posterior margin is free, and forms an arch, extending from one side of the pharynx to the other, but the arch is interrupted in the centre by the conical projection of varying size, called the uvula. Laterally the soft palate is intimately connected on each side with two prominent folds, called the palatine arches.

The more anterior, termed the **glosso-palatine arch** (O.T. **anterior pillar of the fauces**), passes below into the side of the tongue. Traced upwards, it runs on to the inferior surface of the soft palate, and is continuous with the margin of the uvula. The free posterior margin of the soft palate passes into the **pharyngo-palatine arch** (O.T. **posterior pillar of the fauces**), which passes downwards for some distance on the side wall of the pharynx.

The two palatine arches on each side are 7-8 mm. apart, and on the side wall, between each pair, there is a fossa, occupied in part by the palatine tonsil. This region belongs properly to the pharynx, and will be described in detail when that part is dealt with.

The superior surface of the soft palate forms a continuation backwards and downwards of the floor of the nasal cavity, and constitutes the floor of the nasal

part of the pharynx. It is covered by a prolongation of the nasal mucous membrane, partly ciliated in character.

In the fœtus the whole of the epithelial covering of the soft palate is ciliated, but after birth the ciliated epithelium is largely replaced by stratified squamous epithelium, except at the margin of the palate.

Structure.—The framework of the soft palate is formed of a strong, thin, flat, fibrous sheet, called the palatine aponeurosis, which is confined to the anterior part of the soft palate, constituting a common tendon for the palatine muscles. Its anterior margin is united to the posterior edge of the horizontal parts of the palatine bones. With the exception of the aponeurosis of the tensor veli palatini which passes into its lateral part, the muscles do not, as a rule, reach further forwards than to within 8 or 10 mm. of the posterior edge of the hard palate.

The muscles entering into the formation of the soft palate are the mm. pharyngo-palatini, uvulæ, levatores veli palatini, tensores veli palatini, and glosso-palatini. For the details of the attachments and arrangement of these muscles, see p. 466.

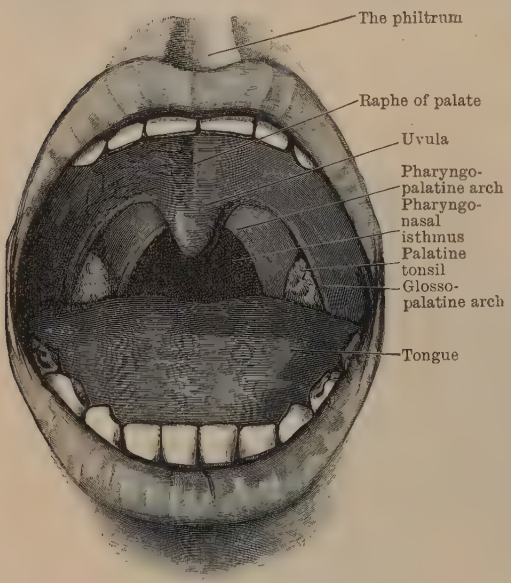

FIG. 855.—OPEN MOUTH SHOWING PALATE AND PALATINE TONSILS.

It also shows the two palatine arches, and the pharyngo-nasal isthmus, through which the nasal part of the pharynx, above, communicates with the oral portion of the pharynx, below.

The anterior part of the soft palate for 8 or 10 mm. ($\frac{1}{3}$ in.) contains practically no muscular fibres; it is composed of the palatine aponeurosis, covered by an extremely thick layer of glands on the inferior surface and by mucous membrane on both surfaces. This anterior portion is much less movable than the rest of the soft palate, and forms a relatively horizontal continuation backwards of the hard palate, stretching across between the two medial pterygoid laminæ. Upon this portion chiefly the tensores veli palatini muscles act. The posterior and larger part contains muscular fibres in abundance, slopes strongly downwards, and is freely movable, and upon it the remaining palatine muscles act.

The **mucous membrane** of the inferior surface of the palate, which is covered by stratified squamous epithelium, is firmer and more closely adherent in front, near the rugæ, than behind, near the soft palate.

Mucous glands, the orifices of which can be seen as dots with the naked eye, are extremely abundant in the soft palate, and in the posterior half of the hard palate, except near the raphe. They are wanting in the anterior part of the palate, where the mucous membrane is particularly dense.

The **plicæ palatinæ** (which correspond to more strongly developed ridges in carnivora, etc.) are very well marked in the child at birth, although, perhaps, relatively less distinct in the fœtus of five or six months; in old age they become more or less obliterated and irregular. At birth, also, and in the fœtus, the incisive pad at the anterior end of the raphe is continued over the edge of the gum into the frenulum of the upper lip.

The **uvula** is composed chiefly of a mass of racemose glands and connective tissue covered by mucous membrane, and containing a slender prolongation of the uvular muscle in its upper part.

The **vessels** of the palate are :—

(1) Branches from the **descending palatine artery**, a branch of the internal maxillary artery.

Of these, some small vessels, the **lesser palatine arteries**, emerge from the smaller palatine foramina, and are distributed to the palatine tonsil and palate, and anastomose with branches of the ascending pharyngeal artery.

The largest branch, **greater palatine artery**, emerges through the great palatine foramen, and runs forwards over the lateral margin of the hard palate, about $\frac{1}{4}$ in. from the alveolar margin, as far as to the incisive foramen, where it anastomoses with the naso-palatine artery.

(2) **Posterior nasal septal artery**, a small vessel which enters through the incisive foramen.

(3) **Ascending palatine artery**, from the external maxillary, which anastomoses by a ramus tonsillaris with the descending palatine.

(4) Branches from the **ascending pharyngeal artery**, which enter the soft palate.

(5) Branches from the **rami dorsales linguæ** of the lingual artery, which pass in the glosso-palatine fold to the palatine tonsil and soft palate.

The **nerves** are all derived from branches from the spheno-palatine ganglion.

(1) **Nervi palatini.** The most important of these is the **nervus palatinus anterior,** which passes through the great palatine foramen, and divides in the roof of the mouth into branches which run in grooves on the hard palate and extend forwards nearly to the incisor teeth.

The others are the **nn. palatini medius** and **posterior,** which emerge from the smaller palatine foramina, and are distributed to the hard and soft palate.

(2) **N. nasopalatinus** (Scarpæ). This nerve sends branches to the palate through the incisive foramen, which join with branches from the anterior palatine nerves.

For the **motor** nerves to the muscles of the soft palate, see p. 467.

The **lymph-vessels** of the palate pass lateral to the tonsil and the isthmus of the fauces to the upper deep cervical lymph-glands.

Isthmus Faucium.—The **isthmus of the fauces** is the aperture through which the mouth communicates with the oral part of the pharynx (Fig. 855). It is bounded at the sides by the glosso-palatine arches, above by the inferior surface of the soft palate, and below by the dorsum of the tongue; in width it corresponds pretty closely to the cavity of the mouth.

The **arcus glosso-palatini** (O.T. **anterior pillars of the fauces**) are two prominent folds of mucous membrane which bound the isthmus of the fauces on each side (Fig. 855). Each contains a glosso-palatine muscle in its interior. They are continuous above with the inferior surface of the soft palate, a little way (about 8 mm.) anterior to its free edge, and near the base of the uvula, and they pass downwards and slightly forwards to join the side of the tongue a little behind its middle.

The **pharyngo-palatini arches** (O.T. **posterior palatine arches**) are two vertical folds of mucous membrane which pass from the soft palate to the side wall of the pharynx. Each contains a muscle, the pharyngo-palatinus. The pharyngo-palatine arches are described in connexion with the palatine tonsil (p. 1138).

Gingivæ.—The **gums** are composed of the firm connective tissue which covers the alveolar borders of the maxillæ and mandible and surrounds the necks of the teeth. In structure they consist of dense fibrous tissue, inseparably united to the periosteum, covered by mucous membrane. They are richly supplied with blood-vessels, but sparsely with nerves, and are covered by stratified squamous epithelium. Around the neck—or more correctly the base of the crown—of each tooth, the gum forms a free overlapping collar, and at this part particularly it is closely studded with small papillæ, visible to the naked eye.

In thickness it usually measures from 1 to 2 mm.

DENTES.

The teeth are hard structures, rooted in the alveoli of the upper and lower jaws, of different form and shape, and appearing in two sets, a deciduous (milk teeth) and a permanent.

General Form and Structure.—Each tooth consists (Fig. 856) of (1) the **corona dentis** or **crown**, the portion projecting above the gum. It varies in shape in the different teeth, and may be chisel-shaped, conical, or flattened and broad. It bears on its masticating surface a number of tubercles, the **tubercula coronæ** (O.T. **cusps**), varying in number from two to five in the different teeth; (2) the **collum dentis** or **neck**, the faintly constricted part which is surrounded collar-wise by the gum, and connects the crown with (3) the **radix dentis** or **root**, the portion of the tooth embedded in the alveolus of the jaw. In the majority of teeth, the root is single, or nearly so, and consists of a long, tapering, conical, or flattened piece, perfectly adapted to the alveolus in which it lies. In the molar teeth (and in some of the others occasionally) the root is divided into two or three tapering or flattened roots or fangs. At the apex of each root there can be made out, even with the naked eye, a minute opening, the **foramen apicis**, through which the vessels and nerves enter the tooth.

Within each tooth is a cavity of some size, the **cavum dentis** or **tooth cavity**, which is filled in the natural state by the loose vascular and connective tissue

known as the **pulpa dentis** or **tooth pulp**. The tooth cavity gradually narrows, and is prolonged into each root of the tooth as a slender tapering passage, the **canalis radicis** (root-canal), which opens at a minute foramen, the **foramen apicis**. Through these foramina and root-canals the vessels and nerves pass to the interior of the tooth.

Short diverticula of the pulp cavity are prolonged into the bases of the tubercles in the molar and premolar teeth, and in the incisors also there are similar slight prolongations of the cavity towards the angles of the crown.

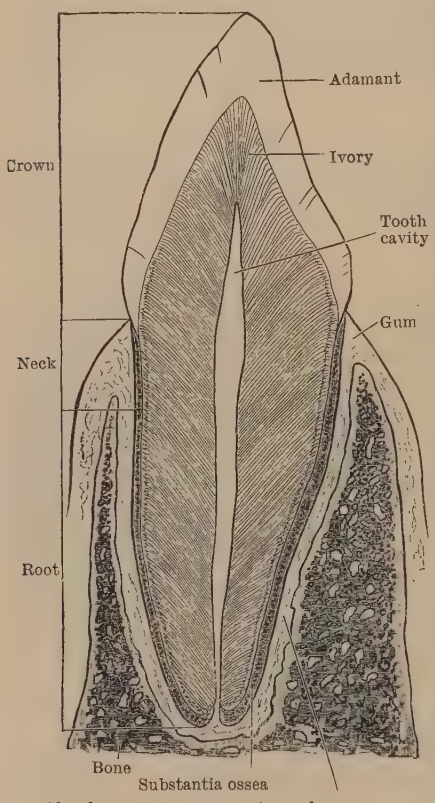

FIG. 856.—VERTICAL SECTION OF CANINE TOOTH to illustrate its various parts and its structure.

The roots of the teeth are embedded in the **alveoli** of the jaws, to which they are firmly united (Fig. 856) by a highly vascular layer of connective tissue—the **periosteum alveolare**. This is attached to the wall of the alveolus on the one hand and to the root of the tooth on the other, whilst above it is continuous with the connective tissues of the gum.

So accurately are the root and the alveolus adapted to each other over their whole extent, and so firmly does the periosteum bind them together, that, under normal conditions, the tooth is quite firmly fixed in the bone, and no movement of the root within the alveolus can take place; the vessels and nerves entering at the apex are thus secured against pressure or strain.

When, however, the alveolar periosteum is inflamed it becomes swollen and exquisitely sensitive; the tooth, as a result of the swelling, is pushed partly out of its socket, its crown projects above those of its neighbours, and strikes against the opposing tooth when the mouth is closed, giving rise to much pain and discomfort.

The **neck** can scarcely be recognised as a distinct constriction in the permanent teeth; it corresponds to the line along which the gum and alveolar periosteum meet, or along which the gum is united to the tooth; but, as already pointed out, the gum does not stop at the neck, but forms a free fold which surrounds the base of the crown collarwise for a short distance. The outline of the margin of the gum opposite the labial and lingual surfaces of the crown is usually concave, but opposite the contact surfaces of the tooth it is convex, and reaches much nearer to the edge of the crown than on the other surfaces.

Tartar is a hard calcareous deposit from the saliva (salivary calculus), often found on the teeth near their necks. It is composed of lime salts, and its deposit is largely determined by the presence of organisms (leptothrix, etc.) in the mouth.

STRUCTURE OF THE TEETH.

Each tooth consists of two chief portions—namely, the **substantia eburnea** (**ivory**, O.T. **dentine**) derived from the connective tissue, and the **substantia adamantina** (**adamant**, O.T. **enamel**) from the epithelial layer of the mucous membrane. The **substantia eburnea** constitutes the chief mass of the tooth, whilst the **substantia adamantina** forms a cap for the crown. There is also found in the teeth another special tissue—the **substantia ossea** (O.T. **cement**), a form of modified bone—encasing the roots. The cement is in turn united to the alveolar wall by a layer of periosteum like connective tissue, the periosteum alveolare (periodontal membrane).

Both **ivory** and **adamant**, but particularly the latter, are the hardest and most resistant structures in the body, and are thus specially fitted for the functions which they have to perform.

The **substantia adamantina** is the dense, white, glistening layer which forms a cap, thickest over the tubercles, for the crown of each tooth (Fig. 856). At the neck it ceases gradually, being here slightly overlapped by the substantia ossea.

It is composed chiefly of phosphate and carbonate of lime. "The **substantia adamantina** is to be regarded as an inorganic substance composed of lime salts, which have been deposited in particular patterns and formed under the influence of organic tissues, which have themselves disappeared during its formation" (Tomes).

The adamantine substance consists of minute, solid, calcified hexagonal prisms, **prismata adamantina**, radiating from the surface of the ivory to the surface of the crown, on which they terminate by free ends, and most of them reach from the ivory to the surface of the crown without interruption. The prisms are held together by the smallest possible amount of calcified matrix (Tomes). In old teeth the cap of adamant is often worn away over the tubercles, the ivory is then exposed, and is easily recognised by its yellowish colour, which contrasts strongly with the whiteness of the adamant.

Whilst adjacent adamantine prisms are in general parallel to one another, they do not usually take a straight, but rather a wavy course, and in alternate layers they are often inclined in opposite directions, thus giving rise to certain radial striations seen by reflected light (Schreger's lines). Certain other pigmented lines, more or less parallel to the surface, are also seen in the adamant (brown striæ of Retzius). They are due to true pigmentation (Williams), and mark the lines of deposit of the adamant during its development. The adamantine prisms are more or less tubular in certain animals—viz., in all marsupials except the wombat, in the hyrax, certain insectivora, and certain rodents.

Cuticula dentis (O.T. **Nasmyth's membrane**) is an extremely thin (1·5 μ) cuticular layer which covers the adamant of recently-cut teeth, and is very indestructible, resisting almost all reagents. Two chief views are held as to its origin. One that it is the last formed layer of adamant, which has not yet been calcified, and therefore the final product of the adamant cells. The other that it is produced by the outer layer of cells of the adamant organ. This latter seems to be the more probable view.

Substantia eburnea (ivory) is the hard and highly elastic substance, yellowish white in colour, which forms the greater part of the mass of every tooth (Fig. 856). Like the adamant it is highly calcified, but it differs from it in containing a very considerable amount of organic matter and water incorporated with its salts, which are chiefly phosphate and carbonate of lime.

Fresh human ivory contains 10 per cent of water, 28 per cent of organic and 62 per cent of inorganic material. The organic matter is composed chiefly of collagen, and to a less extent of elastin. The inorganic matter consists of (1) calcium phosphate (with a trace of fluoride), (2) calcium carbonate, and (3) magnesium phosphate, the percentages present in dried dentine being 66·72, 3·36, 1·08, respectively.

Ivory consists of a homogeneous, highly calcified, organic matrix, everywhere traversed by tubes—the **canaliculi dentales**—which give to this tissue a finely striated appearance, the striæ usually running in wavy lines. The canaliculi begin by open mouths on the wall of the pulp cavity, whence they run an undulating and spiral course, towards the periphery of the ivory. They give off fine anastomosing branches, and occasionally divide into two.

The canaliculi dentales are generally described as being lined by special sheaths (dentinal sheaths of Neumann) which are composed of a most resistant material, and possibly are calcified.

The canaliculi dentales are occupied by processes, prolonged from the outermost cells of the pulp—called after their discoverer, **Tomes' fibrils** (dentinal fibrils), and they are probably sensory in function.

The concentric **lines of Schreger**, frequently seen in the ivory, are due to bends in successive canaliculi along regular lines running parallel to the periphery of the ivory. Other lines (the incremental lines of Salter), due to imperfect calcification, are found arching across the substance of the ivory, chiefly in the crown. There must also be mentioned the **interglobular spaces**, intervals left in the ivory, as a result of imperfect calcification, bounded by the fully calcified surrounding tissue, the contour of which is in the form of a number of small projecting globules. These interglobular spaces are very numerous in the outer or "granular layer" of the ivory, particularly beneath the osseous substance.

The **substantia ossea** (O.T. **cement**) is a layer of modified bone which encases the whole of the tooth except its crown. It begins as a very thin stratum, slightly overlapping the adamant at the neck. From there it is continued, increasing in

amount, towards the apex, which is formed entirely of this substance. It is relatively less in amount in the child, and increases during life. In places the ivory seems to pass imperceptibly into the substantia ossea, the "granular layer" marking the junction of the two, and some of the canaliculi dentales are continuous with the lacunæ of the substantia ossea. Like true bone, it is laminated, it possesses lacunæ, canaliculi, and, when in large masses, it may even contain a few Haversian canals.

The **pulpa dentis** is composed of a number of branched connective tissue cells, the anastomosing processes of which form a fine network, containing in its meshes a jelly-like material, in addition to numerous vessels and nerves, but no lymph-vessels. The most superficial of these cells are arranged in the young tooth as a continuous layer of columnar, epithelium-like cells, lying on the surface of the tooth pulp against the ivory; they are known as **odontoblasts**, for they are the active agents in the formation of the ivory. The vessels of the tooth pulp are numerous, and form a capillary plexus immediately within the odontoblasts. The nerves form rich plexuses throughout the pulp, but their exact mode of ending is unknown.

The **periosteum alveolare** is a layer of connective tissue free from elastic fibres, but well supplied both with blood-vessels and nerves, which fixes the root of the tooth in the alveolus, being firmly united by perforating fibres of Sharpey, to the substantia ossea on the one hand, and to the bone of the alveolus on the other. It establishes a communication between the bone of the jaw and the substantia ossea, and it is continuous with the tissue of the gum. Its blood comes chiefly from the arteries, which subsequently enter the apical foramina for the supply of the tooth pulp, but in part also from the vessels of the surrounding bone and of the gum (hence the relief obtained in dental periostitis by lancing the gum).

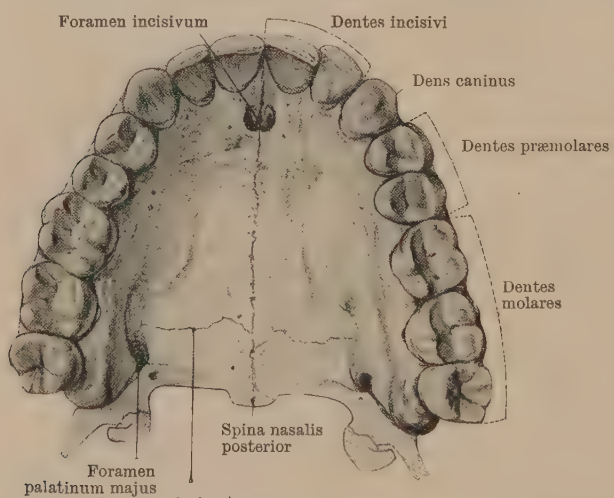

FIG. 857.—THE HARD PALATE AND UPPER PERMANENT TEETH, VIEWED FROM BELOW.

DENTES PERMANENTES.

Names and Numbers of the Teeth.—The two rows, upper and lower, contain the same number of teeth, and of similar varieties. The permanent teeth are thirty-two in number, eight above and eight below on each side. Each set of eight consists of two incisor teeth (dentes incisivi), a medial and a lateral, a single canine (dens caninus), two premolars (dentes præmolares, anterior and posterior), and three molars (dentes molares, first, second, and third), arranged in that order from the median plane. When the dentition is perfect each set is bilaterally symmetrical. The "dental formula" showing the number of teeth of each class above and below on one side is therefore in man :—

$$i.\ \tfrac{2}{2},\ c.\ \tfrac{1}{1},\ pm.\ \tfrac{2}{2}\ m.\ \tfrac{3}{3}.$$

Descriptive Terms.—The part of a tooth which comes in contact with the teeth of the opposite jaw is known as the **facies masticatoria** (grinding or masticating surface) (Fig. 857). The surface in contact with or looking towards its predecessor in the row is known as the **facies medialis** in incisors and canines, **facies anterior** in premolars and molars; the opposite surface is known as the **facies lateralis** in incisors and canines, **facies posterior** in molars and premolars. The surface which looks towards the tongue is the **facies lingualis** (lingual surface), and that towards the lips and cheek, the **facies labialis** (labial surface) or **facies buccalis** (buccal surface). The portion of a tooth which touches its neighbour in the same row is known as the **facies contacta** (contact surface).

Dentes Incisivi (Figs. 858 and 859).—In the incisor teeth the **crown** is chisel-shaped, the labial surface convex in all directions, the lingual surface concave,

the edge chisel-like and, when first cut, surmounted by three small tubercles separated by two grooves. These tubercles, however, are soon worn down, and the edge becomes straight or nearly so. The upper incisors usually overlap the lower

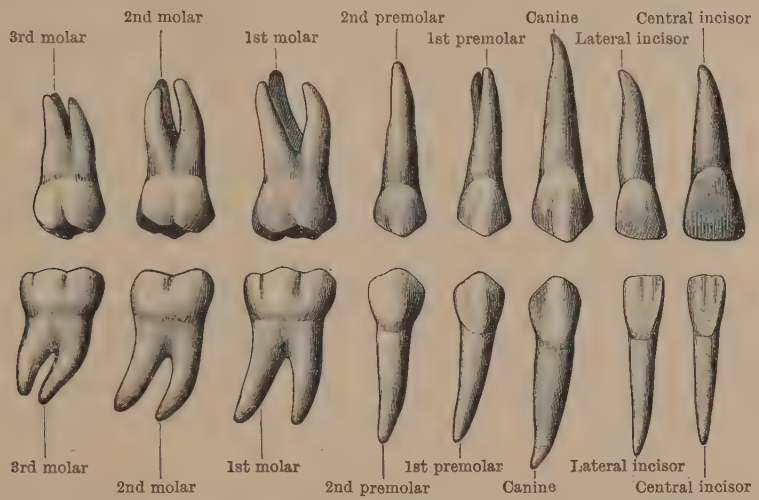

FIG. 858.—THE PERMANENT TEETH OF THE RIGHT SIDE, LABIAL OR BUCCAL SURFACES.

The upper row shows the upper teeth, the lower row the lower teeth. The wide vertical "labial ridge" is distinct on the upper canine and premolar teeth.

ones and hence the cutting edge is bevelled, on the lingual aspect of the former, and on the labial aspect of the latter. The upper, and particularly the central upper incisors, are of large size, and slope somewhat forwards; whilst the lower incisors, all of nearly equal size, are much smaller—being the smallest of all the

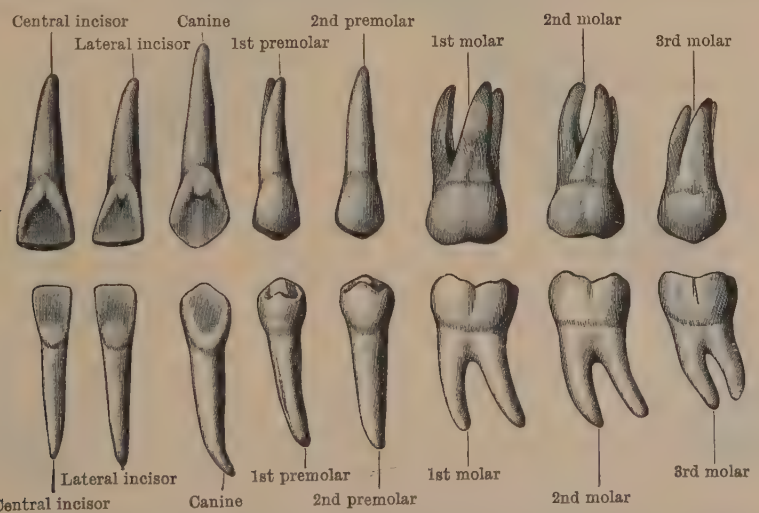

FIG. 859.—THE PERMANENT TEETH OF THE RIGHT SIDE, LINGUAL SURFACES.

The upper row shows the upper teeth, the lower row the lower teeth. The cingulum is distinct on the upper incisors and both canines, the lingual tubercle on the upper lateral incisor and the upper canine.

teeth—and are placed vertically. The roots of the incisors are single, though a groove is occasionally seen on each side, suggesting a division.

The central upper incisors are very much larger than the lateral upper incisors (Fig. 858), but in the mandible the opposite is the case, the lateral incisors being slightly the larger. In all incisors the lateral angle of the crown is more rounded than the medial. The concave lingual surface of the crown in the upper incisors is usually limited towards the gum by a Λ-shaped ridge (Fig. 859), known as the **cingulum**. The two limbs of the Λ are continued up along the sides of the lingual surface, whilst the apex is turned towards the gum; and here, particularly in

the lateral incisor, there is often developed a small **lingual tubercle** (Fig. 859). The cingulum is rarely found on the lower incisors.

The roots of the upper incisors and canines are conical and rounded (the lateral incisors and canines not so distinctly as the central incisors) (Fig. 858), whilst those of the mandible are flattened from side to side (medio-laterally).

Dentes Canini.—In the four **canine teeth** (Figs. 858 and 859) the **crown** is large and conical, corresponding closely in general form to a very large central incisor with its angles cut away. The labial surface is convex, the lingual usually somewhat concave, and both surfaces show a slight ridge extending from the base of the crown to the point. The root is single and long, particularly in the upper canine, the root of which is longer than that of any other tooth, and produces the canine eminence on the anterior surface of the maxilla. The upper canines are larger than the lower ones, and are known as the "eye teeth."

The upper canine presents on its lingual surface a well-marked cingulum, and often a distinct lingual tubercle; in addition, there is usually a median ridge running from the point of the crown to the apex of the cingulum, which is separated from the lateral part of the cingulum on each side by a slight depression. These points are neither so well marked, nor so constant, in the lower as in the upper canine.

Of the two margins sloping away from the apex of the crown, the lateral is the longer in both teeth. After it has been a little worn the lower canine is less distinctly pointed than the upper; its root is also more flattened.

Dentes Præmolares (Figs. 858 and 859). — The **crown**, unlike that of the incisors and canines, is flattened antero-posteriorly, and shows a flat chewing

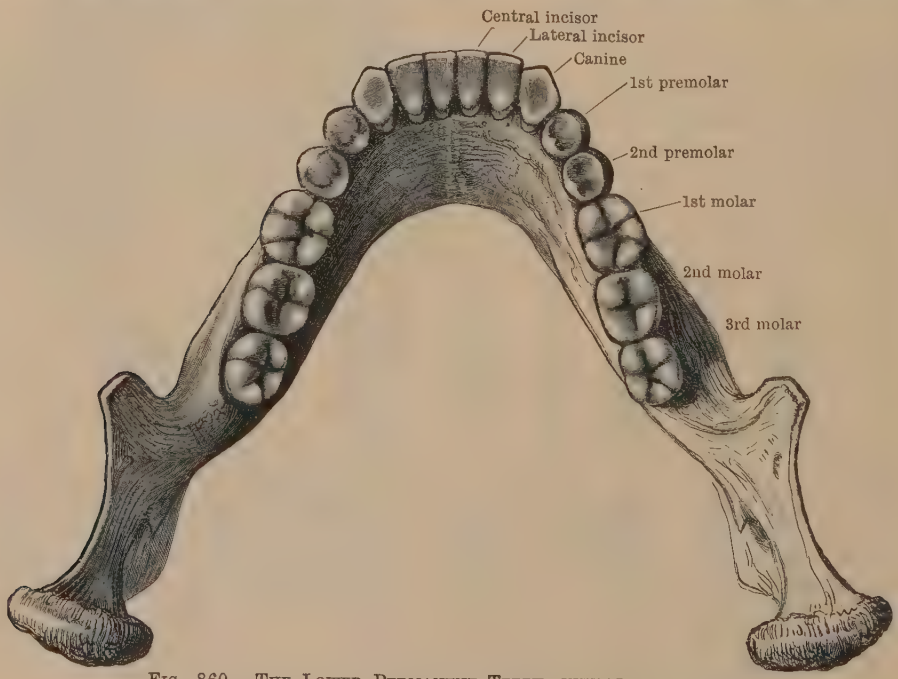

Fig. 860.—The Lower Permanent Teeth, viewed from above.

surface, which is characterised by the presence of two tubercles (O.T. cusps) (Fig. 860), one, the larger, placed on the buccal, the other on the lingual side. The buccal and lingual surfaces are both convex. The **root** is single, but is, as a rule, flattened antero-posteriorly and grooved, showing in this a tendency to division, which often actually takes place in the first upper premolar. In the upper premolars the two tubercles are large and are separated from one another by a distinct antero-posterior fissure (Fig. 857); in the lower premolars, on the other hand, the separation between the two tubercles is not a continuous fissure, but two dimple-like depressions separated by a ridge which joins the two tubercles (Fig. 860). In the upper premolars, therefore, the two tubercles are separated by a fissure, in the lower they are united by a central ridge.

The first premolar is occasionally slightly larger than the second, in the upper but not in the lower set. The labial surface of the crown is usually somewhat larger than the lingual surface in all premolars. As a general rule, in the lower premolars the labial surface of the crown is sloped medially near the masticating surface. The first can usually be distinguished from the second by the fact that, while the lingual tubercle and surface are smaller than the labial in the first premolar, they are nearly of the same size in the second. In addition, the root of the first upper premolar is bifid or nearly so, and its labial ridge is fairly distinct, but is indistinct in the second. In the first lower premolar the lingual tubercle and surface are very small, in fact the tubercle is quite rudimentary. It should, however, be added that it is often extremely difficult to identify the various premolars.

Dentes Molares.—The **molar teeth** are distinguished as first, second, and third molars. The last in each jaw is also known as the **dens serotinus**, late appearing (*sēro* = late). All the molars are characterised by the large size of the crown and the possession of three or more trihedral tubercles on the masticating surface (Figs. 858 and 859). They are the largest of all the teeth. They diminish in size, as a rule, from the first to the third. In shape the crown is more or less quadrangular, with convex labial and lingual surfaces. The roots are either two or three in number, but frequently in the last molars they are united to a varying degree.

The molars of the maxilla and mandible differ considerably in detail. Normally the **upper molars** possess three roots (Figs. 858 and 859), whilst the **lower molars** have two at most. The number of tubercles, though not so reliable a guide as the form of the root, is also generally sufficient to distinguish them. In the upper molars there are either three or four tubercles, whilst in the lower the number is most commonly five.

In the **upper molars**, the **crown** (Fig. 857) is rhomboidal in shape (*i.e.* quadrangular with the angles not right angles). The labial and the lingual surfaces are convex. The number of **tubercles** is either four or three. On the *first* there are invariably four—two on the labial and two on the lingual side—the anterior lingual of these being connected with the posterior labial by an oblique ridge. The *second* upper molar has either four or three tubercles in about an equal proportion; in the third the number is much more frequently three. The **roots** in the upper molars are three in number, two buccal, and the third lingual, but are occasionally confluent in the third molar.

In the **lower molars**, the **crown** is somewhat cubical. The labial and lingual surfaces are convex, as in the upper molars. The *first*, as a rule, bears five tubercles, two labial, two lingual, and the fifth behind and buccal. The *second* has usually only four tubercles; a fifth, however, is sometimes present. The *third* has either four or five, the former number more frequently than the latter.

The **roots** of the lower molars are two in number, one root anterior, the other posterior, each wide, grooved, and flattened antero-posteriorly, and both are usually recurved in their lower portions. As in the corresponding teeth of the maxilla, the roots of the lower last molars are often more or less united into a single mass.

The upper molars are directed downwards and laterally; whilst the lower molars, which the former partly overlap, slope upwards and medially, with the result that the labial tubercles of the lower molars lie in the groove separating the lingual from the labial tubercles of the upper teeth. As a result of this overlapping, the labial edge of the crown is sharp and the lingual edge rounded in the upper molars; whilst the lingual edge is sharp and the labial edge rounded in the lower set.

The fissures which separate the cusps on the grinding surfaces of the molar teeth are generally continued as faint grooves on the labial and lingual surfaces.

The anterior and posterior surfaces of the upper molars are not in transverse but in oblique planes, sloping strongly postero-medially, and converging in that direction.

Lower Molars.—The **crowns** are more massive than those of the upper molars, and are elongated antero-posteriorly (Fig. 860). A crucial groove separates the four chief tubercles from one another; this bifurcates behind to enclose the fifth, which lies slightly to the labial side of the middle of the tooth.

The **roots** of the lower molars (Fig. 859), two in number, are flattened from before backwards, and very wide. The anterior of these has two root-canals; the posterior but one (Fig. 863). The dens serotinus has commonly two roots like its fellows; occasionally the two are united. In determining the side to which a lower molar belongs, it should be remembered that the deep part of the root is generally curved backwards, and also that the blunter margin of the crown (see above) and the fifth tubercle, if present, are on the labial side.

Dentes Decidui.

The **deciduous teeth** are twenty in number, ten above and ten below, or five in each half of each jaw—namely, two incisors, one canine, and two molars. They may be distinguished from the permanent teeth by their smaller size, their well-marked and constricted necks, and, in the case of the molars, by the wide divergence of their roots (Fig. 861). Otherwise they correspond closely to the same-named teeth of the permanent set. The first upper molar has, however, but three tubercles on its crown—two labial and one palatal; the first lower molar has four—two labial and two lingual; and the crowns of both are flattened from side to side. The second molars of the maxilla have four, those of the mandible five tubercles each. In every case the second are much larger than the first molars. The tubercles are sharper and are separated by deeper fissures or fossæ than those of the permanent teeth, whilst the roots of the deciduous molars, except for their greater divergence, agree with those of the permanent set.

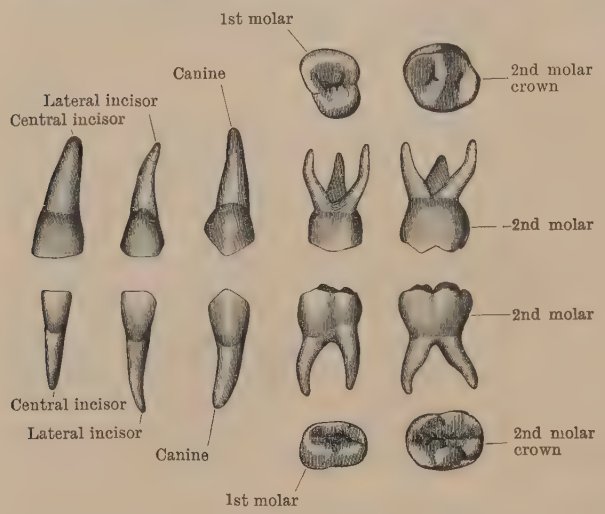

Fig. 861.—The Deciduous Teeth of the Left Side.

The masticating surfaces of the two upper molars are shown above. In the second row the upper teeth are viewed from the outer or labial side. In the third row the lower teeth are shown in a similar manner; and below are the masticating surfaces of the two lower molars. In the specimen from which the first upper molar was drawn the two labial tubercles were not distinctly separated, as is often the case.

The marked constriction at the neck of the deciduous teeth (Fig. 861) is due to a great thickening of the cap of adamant on the crown, and its abrupt termination as the neck is reached. The **adamant**, too, is much whiter as a rule than in the permanent teeth. It should be added that the labial surface of the canines and molars slopes strongly outwards towards the mouth cavity from the neck to the crown, which latter is, as a result, much reduced in width.

The divergence of the roots in the deciduous molars allows the crowns of the permanent premolars to fit in between them before the former molars are shed.

Dentes Decidui and Dentes Permanentes (Deciduous and permanent teeth).—The mouth of the infant at birth contains no teeth, although a number, partly developed, lie embedded in the jaws beneath the gum. Some six months later teeth begin to appear, and by the end of the second year a set, known as the **deciduous teeth** (O.T. **milk teeth**), twenty in number, has been "cut." The individual teeth of this set usually appear at the following ages: the lower central incisors between six and nine months, the upper incisors between eight and ten months, lower lateral incisors and first molars between fifteen and twenty-one months, the canines between sixteen and twenty months, the second molars between twenty and twenty-four months.

Then follows a pause of about four years, during which no visible change takes place in the mouth, although active preparation for further development is going on beneath the gum.

At about the sixth year the next stage in the production of the adult condition begins. It consists in the eruption of four new teeth—the first permanent molars—one on each side, above and below, behind those of the deciduous set. This is followed by the gradual falling out of the twenty deciduous teeth, and the substitution for them of twenty new teeth, which take up, one by one, the vacancies created by the dropping out of each of the deciduous set in the following order :—

First, at about the age of seven the central deciduous incisors fall out; then follow the remaining teeth in the following order: lateral incisors, 1st premolars, 2nd premolars, canines. It will be observed that the eruption of the canine is delayed until the two premolars, which succeed it in the row, are cut, so that it breaks the otherwise regular order of eruption. Finally, the adult condition is attained by the eruption of eight additional teeth — the 2nd and 3rd molars —two on each side, above and below, behind those which have already appeared. All of these —the **permanent teeth** — have appeared by the end of the twelfth or thirteenth year, except the four **dentes serotini** (O.T. **wisdom teeth**), which are usually cut between the seventeenth and twenty-fifth year, but are often delayed until a very much later period, and occasionally never appear. The 1st molar is sometimes popularly known, owing to the date of its eruption, as the "six-year-old tooth," and the 2nd molar as "the twelve-year-old tooth."

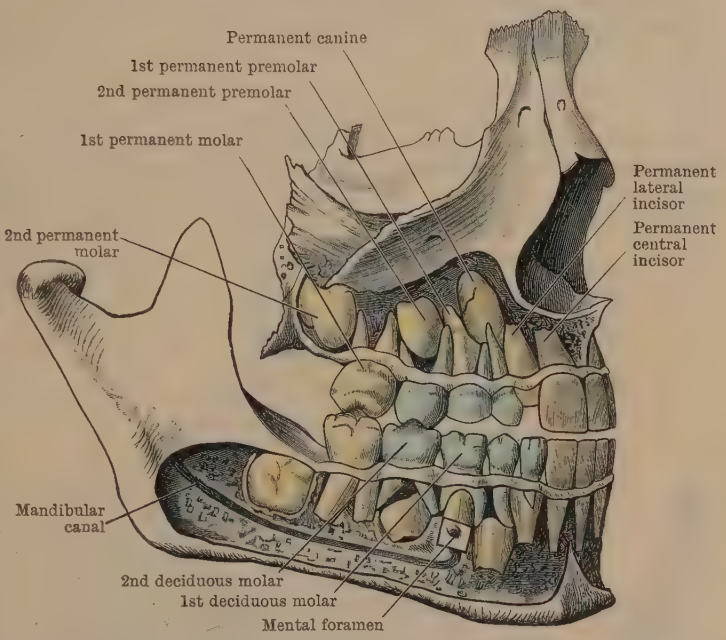

FIG. 862.—TEETH OF A CHILD OVER SEVEN YEARS OLD. (Modified from Testut.)

By the removal of the bony outer wall of the alveoli, the roots of the teeth which have been erupted, and the permanent teeth which are still embedded in the mandible and maxilla, have been exposed. The deciduous teeth are coloured blue, the permanent teeth yellow. It will be seen that the first permanent molars have appeared, the central and lateral deciduous incisors have been replaced by the corresponding permanent teeth in the maxilla, but the deciduous canine and molars have not yet been shed. In the mandible the central deciduous incisor has been replaced by the permanent central; the lateral has not yet been shed, but its permanent successor is making its way up to the surface on its lingual side. In addition, the canine and two molars of the deciduous set persist. The position of the crowns of the permanent teeth between the roots of the deciduous molars, and the deep situation occupied by the permanent canines, should be noted. Observe also the absorption of the root of the lower lateral incisor.

The dates at which the eruption usually takes place may be simply stated as follows for the lower teeth; those of the upper jaw appear a little later:—

1st molars appear soon after the 6th year.				
Central incisors appear	soon after the		7th	year.
Lateral	„	„	8th	„
1st premolar	„	„	9th	„
2nd „	„	„	10th	„
Canine „	„	„	11th	„
2nd molar	„	„	12th	„
3rd „	„	from the	17th	„ to 21st year, or even later.

Variations in the Number of the Teeth.—The presence of an additional tooth is by no means uncommon. It may appear in connexion with the incisor, premolar, or the molar groups. A distinction is drawn between "supernumerary" or imperfect additions to the dentition and "supplemental" teeth which correspond in size with those with which they are associated. When a supplemental incisor appears it has an interesting bearing upon the solution of the much-debated point as to which incisor has disappeared from the primate dentition. A fourth molar is occasionally present.

Arrangement of the Teeth in the Jaws.—The teeth are arranged in each jaw

in a curved row—the **arcus dentalis**—of approximately a semi-oval form (Figs. 857 and 860). The curve formed by the upper teeth, **arcus dentalis superior,** however, is wider than that formed by the lower set, **arcus dentalis inferior,** so that when the two are brought in contact the upper incisors and canines overlap their fellows in front, and the labial tubercles of the upper premolars and molars overlap the corresponding ones of the lower teeth (Fig. 135, p. 129). It will also be seen that, as a rule, the teeth in one jaw are not placed exactly opposite their fellows, but rather opposite the interval between two teeth, in the other jaw (Fig. 135). This arrangement is brought about largely by the great width of the upper central incisors as compared with their fellows of the mandible, which throws the upper canines and the succeeding teeth into a position behind that of the same-named teeth of the lower set. But as the lower molars are larger in their antero-posterior diameter than those of the upper row—and this remark applies particularly to the third molars—the two dental arches terminate behind at approximately the same point.

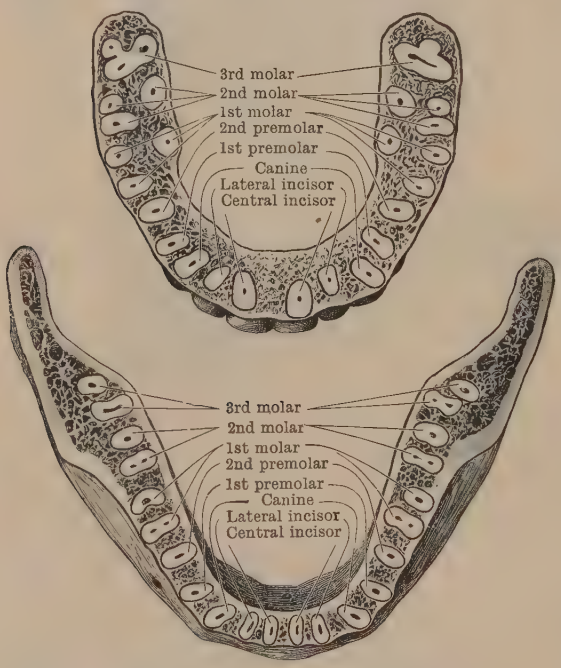

FIG. 863.—HORIZONTAL SECTIONS THROUGH BOTH THE MAXILLA AND MANDIBLE to show the roots of the teeth. The sections were carried through the bones a short distance from the edge of their alveolar borders. The upper figure shows the upper teeth, the lower figure the lower teeth. Note the flattened roots of the lower incisors, the two root-canals in the anterior root of each lower molar, and the confluence of the three roots of the upper last molars.

The upper dental arch is said to form an **elliptical,** the lower a **parabolic curve** (Figs. 857 and 860). The line formed by the masticating surfaces of the upper teeth, as seen on profile view (Fig. 135), is usually somewhat convex, owing largely to the failure of the third molar to descend into line with the others. Similarly the line of the lower teeth is as a rule concave.

In both jaws the crowns of the front teeth are higher (longer) than those of the molars.

LINGUA.

The **tongue** is a large mobile mass, which occupies the floor of the mouth and forms the anterior wall of the oral part of the pharynx (Fig. 865). It is composed chiefly of muscular tissue, and is covered by mucous membrane.

The sense organs of taste are found on its surface. It is an important organ of speech, and it assists in the mastication and deglutition of the food—functions which it is well fitted to perform, owing to its muscular structure and great mobility. In length it measures about three and a half inches (9 cms.) when at rest, but its length and width vary with every change in the condition of the organ.

In describing the tongue we distinguish the following parts: the **corpus linguæ** (body), made up chiefly of striped muscle, and forming the mass of the organ; the **dorsum linguæ** (Fig. 864), which looks towards the palate and pharynx, and is free in its whole extent; the **base,** the posterior wide end which is attached to the hyoid bone; the **apex linguæ,** the pointed and free anterior extremity; the **margo lateralis,** which is free in its anterior half or more, *i.e.* in front of the attachment of the anterior palatine arch (Fig. 864). Finally, the unattached portion on the inferior aspect, seen when the apex is turned strongly upwards (Fig. 867), constitutes the **facies inferior,** or inferior surface; whilst the thick posterior portion, fixed by muscles and mucous membrane to the hyoid bone and mandible, is known as the **radix linguæ** or root.

The **dorsum of the tongue**, when the organ is at rest, is strongly arched antero-posteriorly in its whole length (Fig. 865), the greatest convexity corresponding to the attachment of the glosso-palatine arch. When removed from the body the tongue, unless previously hardened *in situ*, loses its natural shape, and appears as a flat, elongated, oval structure, which gives a very erroneous idea of its true form and connexions.

Both in structure and in function, as well as in embryological history, the dorsum linguæ is divisible into two areas—an anterior or *oral part*, which lies nearly horizontally on the floor of the mouth, and constitutes about two-thirds of the length of the whole tongue (Fig. 865); and a posterior or *pharyngeal part*, the remaining third of the organ, which is placed nearly vertically, and forms the anterior wall of the oral pharynx (Fig. 865). The separation between these two parts, which differ in appearance as well as in direction, is indicated by a distinct V-shaped groove, called the **sulcus terminalis** (Fig. 864), the apex of which is

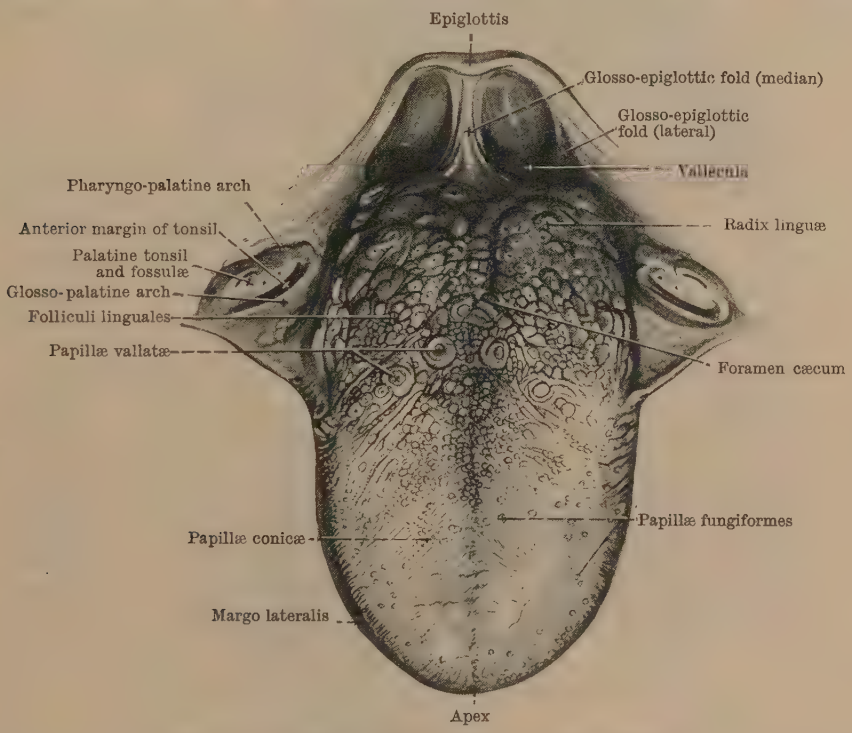

Fig. 864.—Dorsum of Tongue and Palatine Tonsils.

directed backwards, and corresponds to a depression on the surface of the tongue, the **foramen cæcum**, whilst its diverging limbs pass laterally and forwards towards the attachments of the glosso-palatine arch. The foramen cæcum is the remains of a tubular downgrowth formed early in embryonic life, in the floor of the primitive pharynx, from which the thyreoid gland is developed (see p. 49).

The **anterior or oral portion of the dorsum linguæ** (Fig. 864) usually presents a slight median depression, **sulcus medianus**, which ends posteriorly near the foramen cæcum.

Its surface is velvety and is covered with innumerable papillæ; the taste-buds are situated in it, and it is horizontal in position. It is developed from the tissues of the floor of the pharynx immediately behind the first visceral arch.

The posterior portion, on the other hand, has a smooth glistening surface, contains numerous serous glands and small lymph follicles, and is more vertical in position. It is developed from the tissue covering the ventral ends of the second and third visceral arches (see p. 50).

This **posterior portion** (Fig. 864) forms the greater portion of the anterior wall of the oral part of the pharynx (Fig. 865). Its surface is free from evident

papillæ, but is thickly studded with rounded projections, each presenting, as a rule, a little pit, visible to the naked eye, at its centre; the great majority of these **folliculi linguales** (lingual follicles, Fig. 864) are similar to the lymph follicles found in the palatine tonsils; some few are said to be mucous glands; all are covered by a smooth mucous membrane, and they combine to give to this region a characteristic nodular appearance. To this collection of follicles the name **tonsilla lingualis** is applied.

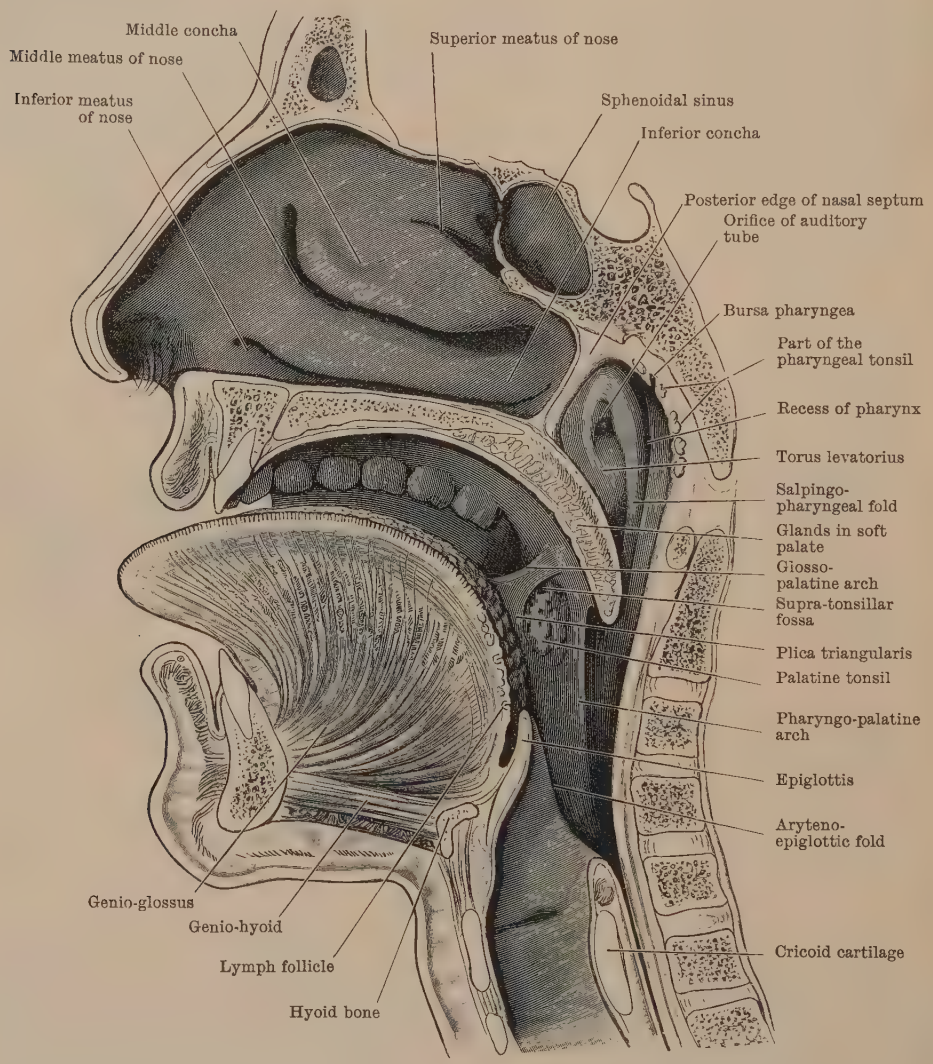

FIG. 865.—SAGITTAL SECTION THROUGH MOUTH, TONGUE, LARYNX, PHARYNX, AND NASAL CAVITY.

The section was slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below, hence the apparently low position of the inferior concha.

On the pharyngeal part of the tongue there are also small papillary projections of the corium, but the epithelium fills up all the intervals between the papillæ, and levels off the surface, so that none are visible to the eye as projections above the general level. Over the anterior part of the tongue, on the contrary, the projections of the corium are large and prominent, and the intervals between them are not filled up by the epithelium, so that the projections stand out distinctly and independently, and in places attain a height of nearly 2 mm. above the general surface.

The *mucous membrane* of this portion of the tongue is separated from the muscular substance by a submucous layer in which the lymph follicles and the mucous glands lie embedded (Fig. 868). At the sides it is continuous with

the tunica mucosa covering the palatine tonsils and the side wall of the pharynx; whilst posteriorly it is reflected on to the front of the epiglottis, forming in the middle line a prominent fold, the **plica glosso-epiglottica** (Fig. 864), at each side of which is a wide depression, the **vallecula**.

On each side is a **pharyngo-epiglottic fold**, which passes from the side of the epiglottis, upwards along the wall of the pharynx, upon which it is soon lost.

Papillæ of the Tongue (Fig. 864).—These are formed by variously shaped projections of the corium of the mucous membrane, covered by thick caps of epithelium. They are of three main varieties: 1, Conical and filiform (*papillæ conicæ, p. filiformes*); 2, Fungiform and lenticular (*papillæ fungiformes et p. lenticulares*); and 3, Vallate and foliate (*papillæ vallatæ et p. foliatæ*).

The **conical and filiform papillæ** (Fig. 864) are the smallest and most numerous,

FIG. 866.

A. Section of a papilla vallata of tongue. B. Section of papillæ conicæ of tongue.

forming as they do a dense crop of minute projections all over the anterior two-thirds of the dorsum, and also upon the superior part of the margin and tip, of the tongue. Posteriorly they are arranged in divergent rows running laterally and forwards from the raphe, parallel to the limbs of the sulcus terminalis. More anteriorly, the rows become nearly transverse, and near the tip irregular. Each papilla is composed of a conical projection of the corium, covered with microscopic papillæ like those of the skin, and covered by a thick long cap of stratified squamous epithelium.

In many of them the cap of epithelium is broken up into several long, slender, hair-like processes, giving rise to the variety known as *filiform papillæ*. The cap of epithelium is being constantly shed and renewed, and an excessive or diminished rate of shedding or renewal, coupled with the presence of various fungi, gives rise to the several varieties of "tongue" found in different diseases.

The conical papillæ are longer and larger than the filiform, and have a wider base. They are situated on the dorsum among the filiform papillæ, and resemble them in their structure.

The conical and filiform papillæ are probably of a prehensible or tactile nature, and are highly developed, and horny, in carnivora.

The **fungiform and lenticular papillæ** (Fig. 864) are larger and redder, but less numerous than the first variety, and they are found chiefly near the tip and margins of the tongue, comparatively few being present over the dorsum generally. Each is in shape like a "puff-ball" fungus, consisting of an enlarged rounded head, attached by a somewhat narrower base. As in the case of the conical papillæ, the corium is studded over with microscopic papillæ, which are buried in the covering of squamous epithelium and do not appear on the surface. Most of the fungiform papillæ, if not all, appear to be furnished with taste-buds, and they are probably intimately connected with the sense of taste. The lenticular papillæ are placed on the margin of the tongue. They are flatter than the fungiform papillæ, and do not contain taste-buds.

The **vallate papillæ** (O.T. **circumvallate**) (Fig. 864), much the largest of all the papillæ of the tongue, are confined to the region immediately in front of the sulcus terminalis and foramen cæcum. Usually about nine to fourteen in number, they are arranged in the form of the letter V, with the apex posteriorly, just in front of and parallel to the sulcus terminalis. One or two of the papillæ are usually placed at the apex of the V, immediately anterior to the foramen cæcum. In appearance a vallate papilla resembles very closely the impression left by the barrel of a small pen pressed on soft wax (Fig. 866). Each is composed of a cylindrical central part (1 to 2·5 mm. wide), slightly tapering towards its base, and flattened on its crown, which projects a little above the general surface of the tongue. This is surrounded by a deep, narrow, circular trench or **fossa**, the outer wall of which is known as the **vallum**. The vallum appears in the form of an encircling collar very slightly raised above the adjacent surface (Fig. 866).

FIG. 867.—OPEN MOUTH WITH TONGUE RAISED, AND THE SUBLINGUAL AND ANTERIOR LINGUAL GLANDS EXPOSED.

The sublingual gland of the left side has been laid bare by the removal of the mucous membrane; to expose the anterior gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the medial aspect of the gland. The vena profunda linguæ is faintly indicated on this side also.

As in the case of the other forms, the vallate papillæ are made up of a central mass of corium, studded with numerous microscopic papillæ on the crowns, but not on the sides, and covered over, as are the surfaces of the fossa and vallum, by stratified squamous epithelium. Into the fossæ open the ducts of some small serous glands (Fig. 866 A).

On the sides of the vallate papillæ, as well as upon the opposed surface of the vallum, are found, in considerable numbers, the structures known as **taste-buds**, the special end-organs of the nerves of taste.

Just anterior to the glosso-palatine arch, on the margin, are usually seen about five or six distinct vertical folds, forming the **folia linguæ**, which are studded with taste-buds. They correspond to the papillæ foliatæ on the side of the tongue in certain animals (rabbit, hare, etc.), in which they form an important part of the organ of taste.

The **apex** and the **margin** of the tongue in front of the attachment of the glosso-palatine arch are free, and lie in contact with the teeth when the tongue is at rest.

The **inferior surface** of the tongue, which is exposed by turning the apex of the organ upwards, is free from visible papillæ, the surface being covered by a smooth mucous membrane. Running along its middle, except near the tip, is a depression, from which a fold of mucous membrane, the **frenulum linguæ**, passes down to the floor of the mouth, and on towards the posterior aspect of the mandible. At each side of the frenulum, and a short distance from it, the large profunda linguæ vein is distinctly seen through the mucous membrane. Further out still are situated two indistinct, fringed folds of mucous membrane, the **plicæ fimbriatæ**, which converge somewhat as they are followed forward towards the tip, near which they are lost.

The **plicæ fimbriatæ** correspond pretty closely to the course of the deep lingual arteries as they run towards the tip; the arteries, however, are deeply placed in the substance of the tongue, at a distance of 3 to 6 mm. from the inferior surface.

The **root of the tongue** is the portion which is connected by muscles and mucous membrane to the mandible and hyoid bone. It is of very considerable extent, and is, with the base, the most fixed part of the organ.

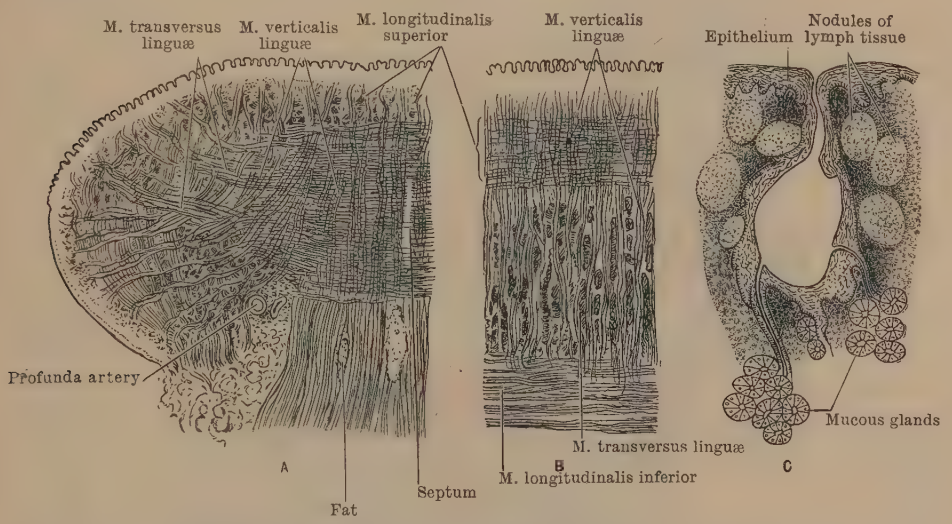

FIG. 868.—A, TRANSVERSE, AND B, LONGITUDINAL VERTICAL SECTION THROUGH THE TONGUE (Krause); C, A LYMPH FOLLICLE FROM POSTERIOR PART OF THE TONGUE. (Macalister, slightly modified.)

Structure of the Tongue.—The tongue is composed chiefly of striped muscular tissue, with a considerable admixture of fine fat. A median septum of connective tissue occupies the central part of the organ. In addition, there are vessels, nerves, glands, and lymph tissue, the whole being covered over by mucous membrane, except at the root (Fig. 868).

The muscular tissue is derived partly from the terminations of the extrinsic muscles—namely, the hyo-glossus, stylo-glossus, genio-glossus, glosso-palatinus, and chondro-glossus; and also largely from the intrinsic muscles—namely, the longitudinalis superior, the longitudinales inferiores, the transversus linguæ, and the verticalis linguæ. These are so arranged that they form a **cortical portion**, made up chiefly of longitudinal fibres—derived, above, from the longitudinalis superior and the hyo-glossus, at the sides, from the stylo-glossus, and, below, from the longitudinales inferiores. This cortex surrounds a central or **medullary portion**, divided into two halves by the median **septum**, and formed in great part by the transverse and vertical fibres, and also by the fibres of the genio-glossi ascending to the dorsum. The muscular fibres derived from these various sources end by being inserted into the deep surface of the mucous membrane.

The detailed description of the extrinsic and intrinsic muscles will be found on page 464.

The **septum** is a median fibrous partition found in the medullary portion only. Anteriorly it usually extends to the apex; whilst posteriorly it grows gradually narrower, and expanding transversely it passes into a broad sheet (the hyo-glossal membrane) which is united to the upper border of the hyoid bone, and gives attachment to the posterior

fibres of the genio-glossus. From the sides of the septum the fibres of the transverse muscle of the tongue arise.

The **mucous membrane** on the anterior two-thirds of the dorsum, and on the free margins, is firm and closely adherent to the underlying muscular substance, the fibres of which are inserted into it. On the posterior third of the dorsum, and on the inferior surface, it is neither so firm nor so closely united to the muscular substance, from which it is separated in both of these situations by a layer of submucous tissue.

The mucous membrane of the tongue, like that of the rest of the mouth, is covered by stratified squamous epithelium.

Glandulæ Linguales.—Numerous small racemose glands are found scattered beneath the mucous membrane of the posterior third of the tongue; and a small collection of similar glands is present at the margin, opposite the vallate papillæ. Small serous glands are also found embedded in the dorsum near the vallate papillæ, into the fossæ of which their ducts open (Fig. 866).

The chief collections of glandular tissue in the tongue, however, are found embedded in the muscle of the under surface, a little way posterior to the apex, on each side of the middle line (Fig. 867). They are known as the **glandulæ linguales anteriores** of Blandin or Nuhn.

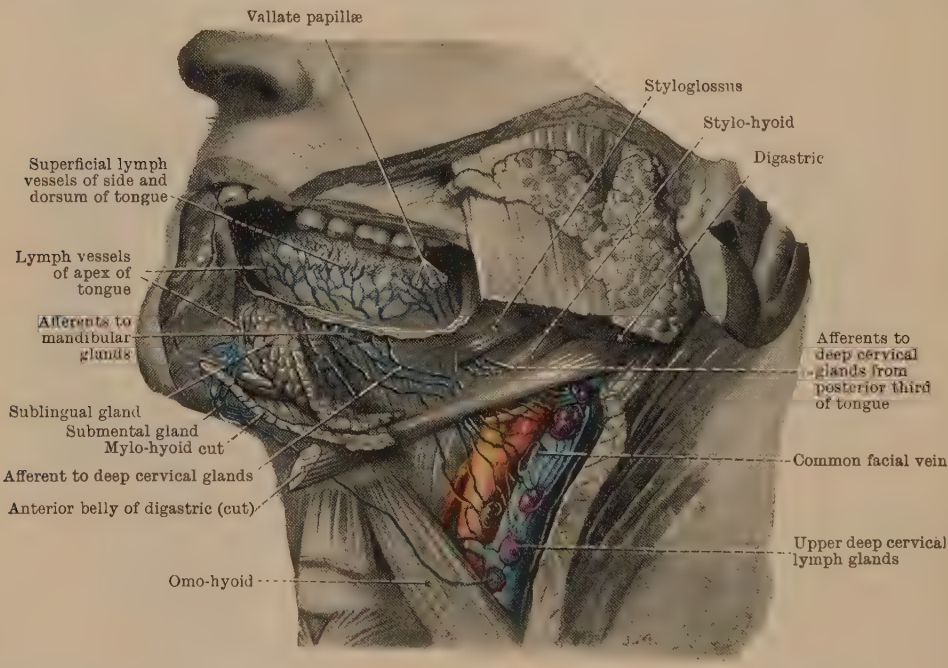

FIG. 869.—LYMPH-VESSELS OF THE TONGUE. (After Poirier and Cuneo, modified.)

These glands are displayed after the removal, from the under surface of the tongue, of the mucous membrane and a layer of muscle fibres about 2 mm. thick which is composed of fibres of the stylo-glossus and the longitudinalis inferior muscles a little distance behind the apex. The anterior lingual glands are oval in shape, often partly broken up by muscular fibres, and they measure from $\frac{1}{2}$ to $\frac{3}{4}$ in. (12 to 19 mm.) in length. They are mixed serous and mucous glands, and they open by three or four very small ducts on the inferior surface of the tongue.

Vessels.—The chief *artery* is the **lingual**. This vessel passes forwards, on each side, medial to the hyo-glossus muscle, and then is continued on to the apex—between the genio-glossus on the medial side and the longitudinalis inferior laterally—under the name of the **a. profunda linguæ**. Anteriorly it is covered by the fibres of the longitudinalis inferior, and lies $\frac{1}{8}$ to $\frac{1}{4}$ in. from the surface. Near the apex the arteries of opposite sides are connected by a branch which pierces the septum; but otherwise, with the exception of capillary anastomosis, they do not communicate. The **rami dorsales linguæ** of the lingual artery are distributed to the pharyngeal part of the tongue, whilst some twigs of the **ramus tonsillaris** of the external maxillary artery are also distributed in the same region.

The **veins** are: The v. **profunda linguæ**, the chief vein, which lies beneath the mucous membrane at the side of the frenulum, and runs backwards over the hyoglossus with the hypoglossal nerve; two **venæ comites**, which accompany the lingual artery; and two **dorsales linguæ veins** from the back of the tongue. These either unite and form a common trunk, or open separately into the internal jugular vein.

The **lymph-vessels** of the tongue take their origin in an extensive lymph network in the submucous coat, and a smaller network connected with the first, in the muscular substance of

the tongue. The network at the apex, including the tip, margins, and front of the dorsum, is drained by some two to four vessels on each side, which pass downwards by the margin of the genio-glossus muscle and pass laterally to the inferior deep cervical lymph glands. These vessels may be connected with the submental lymph glands also.

From the margins and dorsum of the tongue, behind the former area, and extending back to the vallate papillæ, lymph-vessels pass to the submaxillary lymph glands, and also, on the hyo-glossus muscle, to the upper deep cervical lymph glands, especially to some glands near the bifurcation of the common carotid artery. From the posterior part of the tongue the lymph-vessels pass laterally on each side below the palatine tonsil, and thence follow the course of the tonsillar lymph-vessels to the upper deep cervical lymph glands. Some central vessels, from the median portion of the tongue, pass downwards to the submaxillary glands, and also to the upper deep cervical glands, on the lateral side of the internal jugular vein.

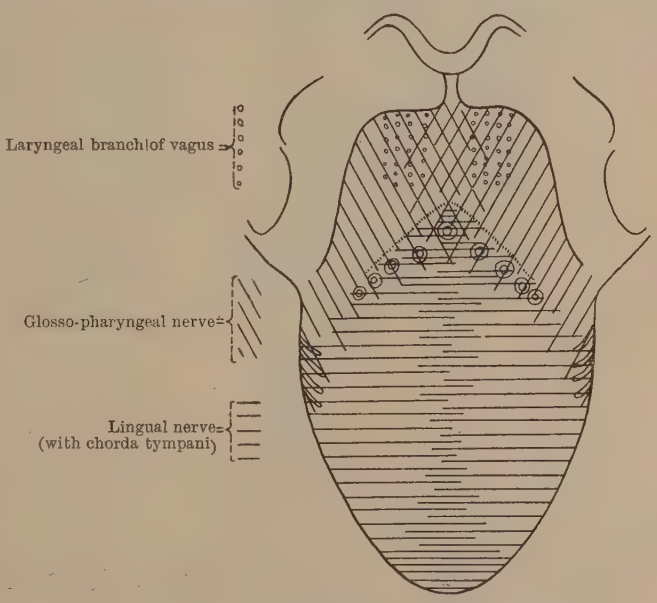

Fig. 870.—Areas of Afferent Nerve Supply of Tongue.

Nerves. — The nerves which supply the tongue are: (1) The **hypoglossal nerve**, the motor nerve of the tongue, which enters the genio-glossus and passes up in its substance to the intrinsic muscles, in which it ends. (2) The **lingual nerve**, a branch of the mandibular nerve, which is accompanied by the **chorda tympani branch** of the facial nerve. The lingual, after crossing the hyo-glossus, breaks up and enters the longitudinalis inferior and genio-glossus muscles, and thus makes its way upwards to the mucous membrane of the anterior two-thirds of the tongue—the lingual itself conferring common sensation on this part, the chorda tympani probably carrying to it taste fibres. (3) The **glosso-pharyngeal nerve** passes forwards beneath the upper part of the hyo-glossus muscle, and sends its terminal branches to the mucous membrane of the posterior third of the tongue, supplying the papillæ vallatæ, and the part of the tongue behind these, with both gustatory and common sensory fibres. (4) The **internal laryngeal nerve** also distributes a few fibres to the posterior part of the base of the tongue, near the epiglottis.

GLANDULÆ.

Numerous organs, differing widely in structure, function, and development, are commonly included under the term **gland**. It may indicate any of the following types:—

(1) Glands producing a visible fluid or semi-fluid secretion, which is discharged from the cells of the gland, either directly or by a duct, on to a free surface, where it is useful chemically or mechanically, or by which it is drained away. Glands of this type connected with the alimentary canal are serous and mucous glands, salivary glands, gastric and intestinal glands, and the liver and pancreas.

(2) The so-called **ductless glands**, which possess no ducts, but secrete some substances, which are directly and gradually transmitted from the cells of the gland to the blood or lymph stream, and are of use in the general metabolism of the body. Such structures are the thyreoid gland, the suprarenal glands, the parathyreoids, and the hypophysis cerebri.

(3) **Cytogenic** or cell-producing glands, not always epithelial, and usually with no distinct duct, consist of aggregations of special cells, enclosed in a more or less definite framework of connective tissue, freely supplied with blood- and lymph-vessels. Glands of this type are concerned in the production, from the cells

in the glands, of special cells, which are liberated from the gland tissue, and pass away from it. Such glands are lymph glands, the bone marrow, and the reproductive glands—testes and ovaries.

Glands may also be classified according to their development, and on this basis the following groups are recognised:—

(1) **Glandulæ epitheliales**, developed from epithelial cells. These may (*a*) possess a duct, in which case they are termed **glandulæ evehentes**; or (*b*) they may be constituted as ductless glands, and they are then termed **glandulæ clausæ**. To this last group belong the thyreoid gland, the hypophysis, and the suprarenal glands.

(2) **Glandulæ vasculares**, developed in connexion with vessels, and not containing epithelial cells. This group includes all the lymph glands, the lymph nodules found in the intestine, the tonsils, the thymus, and the spleen.

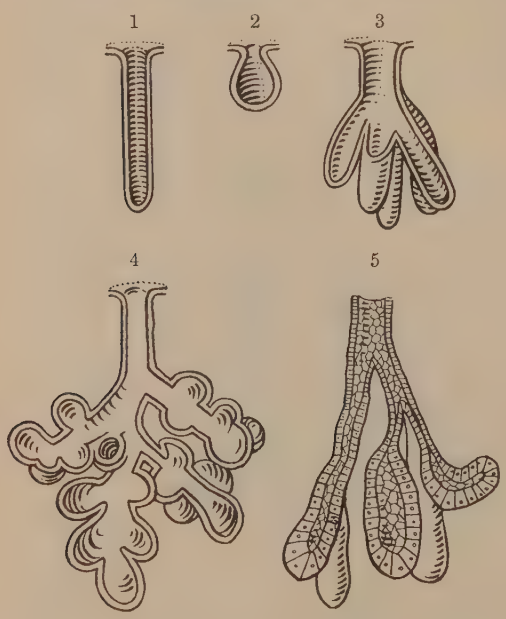

Fig. 871.—Diagram of the Structure of Various Types of Glands.

1. Simple tubular gland.
2. Simple alveolar.
3. Compound tubular.
4. Gland acinus (racemose gland).
5. Section of secreting portion of gland and ducts.

In the following paragraphs only the true glands of the alimentary system — namely, the glands of epithelial origin, characterised by the possession of ducts—are considered.

Such glands may be defined as epithelial organs used for the secretion or excretion of some particular substance or substances from the body. They usually consist of a number of cells, and there may be different kinds of cells in a gland.

The simplest form of this type of gland is an involution of an epithelial surface, which may be of various forms.

The simplest form is a single pocket, of uniform size throughout, forming a simple tubular gland. Of this kind are the intestinal glands in the wall of the small intestine.

In other cases the end of the gland may be widened, forming a sort of pocket, called an alveolus (*alveolus*, small stomach or bag), and this type of gland is known as the simple alveolar gland. It does not exist in the alimentary canal.

In some cases the lower part or fundus of the gland does all the secretion, and the upper part forms a tube or duct that carries the secretion to the surface.

When the outgrowth forming the gland remains undivided, the gland is known as a **simple gland**. It may, on the other hand, break up into two or more branches, and it then is known as a **compound gland**, and this compound gland may be tubular, alveolar, or of a mixed tubular and alveolar form.

When the fundus of the gland at the extremities of the ducts becomes a highly differentiated saccular region, consisting of several enlargements (alveoli) at the end of a duct, it is called an **acinus** (*ăcĭnus*, a berry), from the fancied resemblance it presents to a cluster of grapes at the end of a stalk. A gland formed of several such structures collected together is often called a **compound acinous** or **racemose gland** (*racemus*, a cluster).

General Structure of Glands.—Whilst the small glands, such as those of the mouth and pharynx, are placed in the mucosa or submucosa close to the point at which their ducts open on the surface, the large glands forming distinct masses, often lie at a considerable distance from the points at which their ducts open, and are generally surrounded by special capsules.

Each of these large glands of the acinous type, such as the parotid or submaxillary,

presents the following general arrangement. The gland is made up, as can be seen with the unaided eye, of a number of masses, often as large as peas, which are surrounded and held together by connective tissue. These are known as lobes, and to each a branch of the duct passes. The lobes are in turn made up of a number of smaller masses—lobules—each having a special branch of the lobar duct. These again are composed of smaller lobules, and finally the smallest are made up of a terminal branch of the duct, with a cluster of acini or alveoli leading into it.

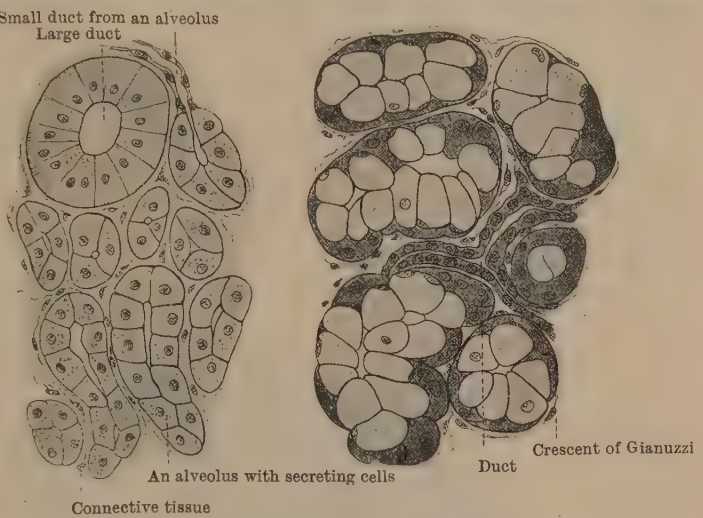

FIG. 872.—SECTION OF A SEROUS GLAND ON THE LEFT, A MUCOUS GLAND ON THE RIGHT SIDE. (Böhm and v. Davidoff.)

In the serous gland the granular secreting cells and the centrally-placed nucleus should be noted. The relatively clear cells, with the dark crescents of Gianuzzi, are distinctive in the mucous gland.

The **acini** or **alveoli** are composed of a basement membrane, often fenestrated or basket-like, formed of flattened cells, on the outer side of which the blood- and lymph-vessels lie. The inner surface of this membrane is lined by the secreting epithelial cells, usually polygonal in shape, which almost completely fill the alveolus. A small lumen, however, is left, into which the secretion of the cells is shed; thence it passes into the duct of the lobule, and thus to the main duct.

The blood- and lymph-vessels, on entering the gland, break up and run, branching as they go, in the connective tissue which conveys them to all parts of the gland.

GLANDULÆ SALIVALES.

Saliva is a clear watery fluid poured by a number of glands into the mouth cavity. It moistens the tongue and the walls of the mouth, and facilitates movements of the tongue in speaking. Mixed with food by mastication it helps in swallowing. It also contains a ferment which plays an important part in digestion, and can transform starch into dextrin.

The glands which secrete it include the small glands of the lips, cheeks, and tongue, and also three large paired glands, the parotid, submaxillary, and sublingual glands. These last alone are usually included in the term salivary glands.

Glandula Parotis.—The **parotid gland**, the largest of the salivary glands, lies on the side of the face, below and in front of the ear, the mastoid process and sterno-mastoid muscle.

It forms a lobulated mass, of a yellowish or light reddish-brown colour, with a large triangular superficial surface. From this mass a process of the gland passes medially behind the ramus of the mandible, almost to the side wall of the pharynx. It is known as the **processus retromandibularis.**

Shape and Relations of the Parotid Gland.—In shape the parotid gland with its deep process is three-sided (Fig. 873), the three surfaces being superficial, anterior, and posterior.

Superficial Surface.—This surface is somewhat triangular in form, though irregular in outline. Its long posterior border lies in front of the external acoustic meatus and the sterno-mastoid muscle, and extends down to the angle of the jaw and the posterior belly of the digastric muscle. Its superior border lies below the zygomatic arch, and the inferior border passes irregularly upwards and anteriorly to join it. The apex, directed anteriorly, forms the facial process of the

gland, and lies on the masseter muscle, and the duct of the gland issues from it, or just below it.

This superficial surface is frequently prolonged downwards over the digastric muscle. It may descend beyond the angle of the mandible, and come into immediate relation with the posterior part of the submaxillary gland, from which it is separated merely by a thin layer of the deep cervical fascia.

Embedded in the superficial surface there are usually found several small rounded lymph glands, which can be distinguished from the gland tissue by the difference in their colour.

The **facial process** of the gland—often of considerable size—is a flat and somewhat triangular portion which runs forwards from the upper part of the front of the gland, and overlaps the masseter muscle to a varying extent. A separated portion of this process, often found lying immediately above the duct, is known as the **glandula parotis accessoria.**

Processus Retromandibularis.—This portion of the gland occupies a deep

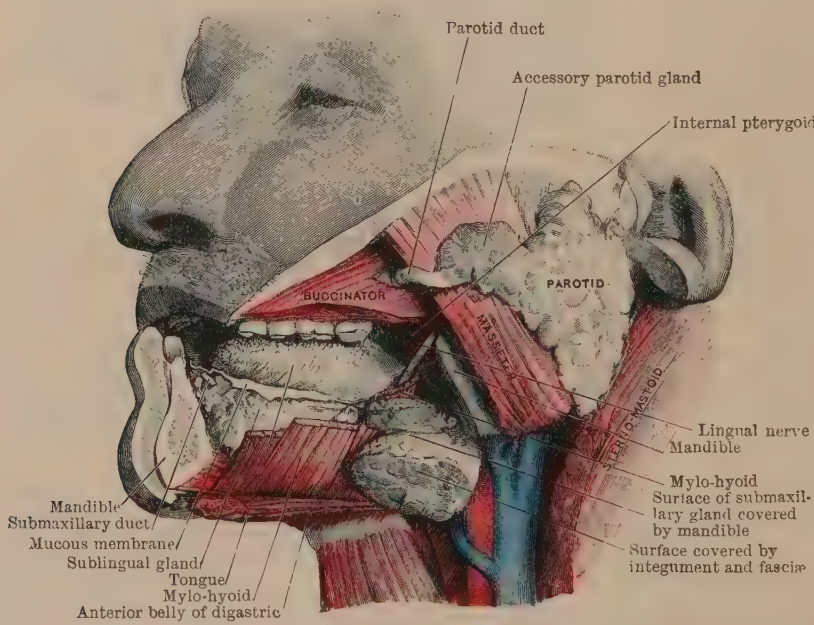

FIG. 873.—THE SALIVARY GLANDS AND THEIR DUCTS.

fossa, called the parotid fossa, of considerable size, which has two nearly vertical sides, an anterior and posterior. These sides converge towards one another and meet deeply, and so form the apex of the fossa. This fact is well brought out by a horizontal section through the head about the middle of the gland (Fig. 874).

From this it will be seen that the posterior wall of the fossa is formed, medial to the sterno-mastoid muscle, by the posterior belly of the digastric and the stylo-hyoid muscles, with the occipital artery, and more deeply still, by the root of the styloid process and the carotid sheath and its contents, and especially by the internal jugular vein, separating the fossa from the vertebral column.

The anterior wall of the fossa is formed by the ramus of the mandible and the masseter and internal pterygoid muscles.

The portion of the gland lying in this fossa—the retro-mandibular or deep process — presents an anterior surface looking forwards, deeply concave, and a posterior surface, irregular in outline, directed backwards and medially.

These surfaces meet medially at the medial border, which may lie so deeply as to be in contact with the side wall of the pharynx. The superior and inferior borders, at the union of the anterior and posterior surfaces, are irregular in outline, and indefinite.

The relations of these two surfaces are as follows:—

The anterior surface is wrapped round the ramus of the mandible, and extends on to the muscles which cover this portion of the bone laterally and medially, that is, on to the masseter and internal pterygoid muscles respectively.

The posterior surface is in contact with the structures which form the posterior wall of the fossa, viz., from the surface medially, with the sterno-mastoid muscle, the mastoid process, the external acoustic meatus, the posterior belly of the digastric muscle, the internal jugular vein, and the root of the styloid process and the styloid muscles. It is often deeply grooved by the posterior belly of the digastric.

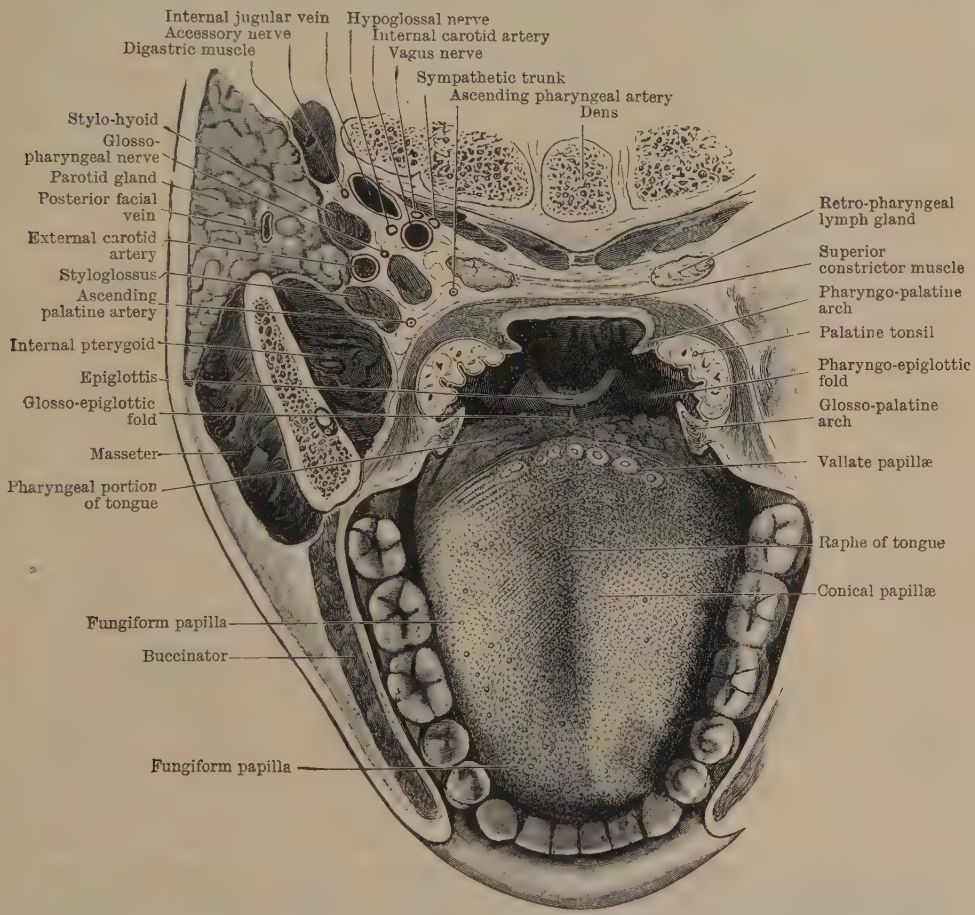

FIG. 874.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS.

The prevertebral muscles and the stylopharyngeus (which is shown just at the medial side of the external carotid artery) are not indicated by reference lines.

The posterior surface is occasionally prolonged medially beyond the lower portion of the styloid process, towards the pharynx. In such cases, the lower part of the styloid process lies in a groove on the posterior surface of the gland.

The gland frequently gives off processes which pass into the intervals between the structures bounding the fossa. Occasionally from its superior end a small process termed the *glenoid lobe* is found, passing into the posterior or tympanic part of the mandibular fossa.

Another runs into the interval between the sterno-mastoid and digastric muscles; and a pharyngeal process is occasionally found extending medially, anterior to the styloid process, towards the side of the pharynx.

A pterygoid extension, between the two pterygoid muscles, cannot properly be said to exist.

Fascia Parotideomasseterica.—The parotid recess is covered over on the one hand, and lined on the other, by fascia. The covering layer is specially known as the **fascia parotideomasseterica**, and both it and the lining layer are derived from the deep cervical fascia, which divides to enclose the gland. The parotideo-masseteric fascia is connected, on the surface, above to the zygoma; posteriorly, to the acoustic meatus and anterior border of the sterno-mastoid; below, it is continuous with the deep cervical fascia, and anteriorly it passes over the masseter, and blends with the fascia buccopharyngea. The fascia forms a lining for the recess, and is united above to the periosteum over the acoustic meatus and posterior part of the glenoid fossa; medially it is connected to the styloid process; whilst below it joins the deep cervical fascia. Taken together, the two layers form a definite capsule which completely encloses the gland. In connexion with the lower and anterior part of this capsule is developed a special flat band, the **stylo-mandibular ligament,** which passes downwards and laterally from the styloid process to the angle of the mandible. It separates the anterior part of the parotid gland from the posterior border of the internal pterygoid muscle; perhaps occasionally, also, from the upper and posterior part of the submaxillary gland.

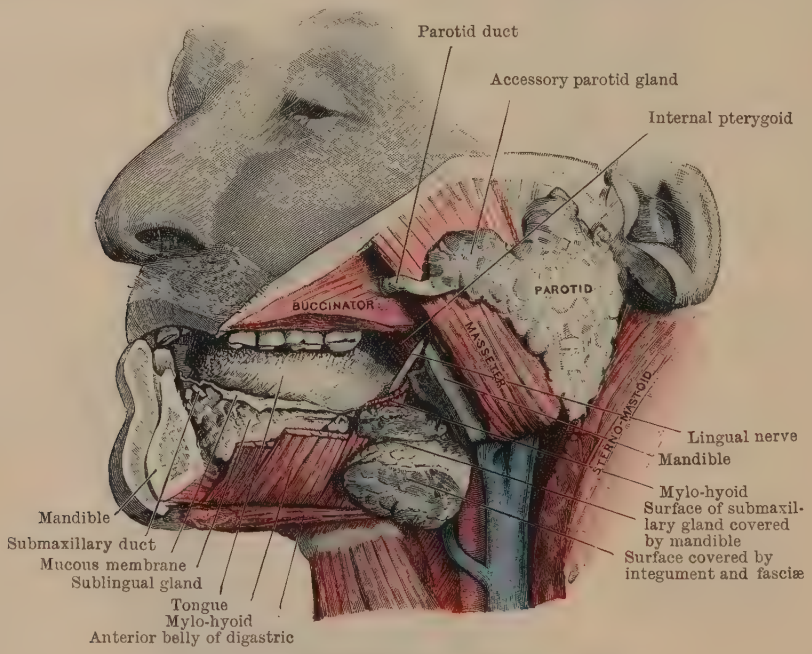

FIG. 875.—THE SALIVARY GLANDS AND THEIR DUCTS.

Ductus Parotideus (Stensen).—The parotid duct (O.T. Stensen's) leaves the anterior border of the gland at its most prominent part (Fig. 875). It first runs forwards across the masseter, below the accessory parotid gland, accompanied by branches of the facial nerve, and the transverse facial artery, which is commonly some distance above, though its relation is variable. Having crossed the masseter, the duct turns abruptly round the anterior border of this muscle and runs inwards through the fat of the cheek, practically at right angles to the first part of its course, to reach the buccinator, which it pierces. Then passing for some distance (5 to 10 mm.) between the buccinator and the mucous membrane, it opens into the vestibule of the mouth by a very small orifice, on a variably developed papilla, opposite the crown of the second upper molar tooth.

The course of the duct can be marked on the side of the face by drawing a line from the inferior edge of the acoustic meatus to a point midway between the ala of the nose and the red of the lip; the middle third of this line corresponds fairly accurately, on the surface, to the course pursued by the duct.

The duct measures from $1\frac{1}{2}$ to $2\frac{1}{2}$ inches (38 to 62 mm.) in length, and $\frac{1}{8}$ inch (3 to 4 mm.) in diameter. The calibre of the duct is very much greater than that of its orifice, which admits only a fine bristle, and for this reason the duct may, to some extent, be looked upon as a

reservoir for the saliva, as well as a duct for its conveyance. In the child it pierces the "sucking pad" on its way to the mouth.

A number of vessels and nerves are found in intimate relation to the parotid gland.

These are: (1) The external carotid artery and its two terminal branches. This artery lies at first in a groove in the inferior and deep aspect of the gland. It then enters the gland substance and lies deeply in it, as far up as to the neck of the mandible, where it divides into its two terminal branches. The superficial temporal artery emerges from the superior superficial part of the gland, and the internal maxillary artery turns inwards and emerges from the deep part of the anterior surface.

The transverse facial artery is given off in the substance of the gland, and emerges from it between the zygomatic arch and the duct.

The posterior facial vein descends in the substance of the gland superficially, and divides in it into the two terminal branches which emerge from the inferior part of the gland.

The facial nerve enters the posterior surface of the gland, slightly below its middle, and runs forwards and laterally, dividing into its main branches within the gland, and lying superficial to the external carotid artery and posterior facial vein. Communicating branches from the auriculo-temporal and great auricular nerves to the facial also traverse the gland substance.

Vessels and Nerves.—The **arteries** which supply the gland arise from the external carotid artery, and from the branches of this artery in relation to the gland.

The **veins** join the posterior facial vein and its tributaries. The **lymph vessels** pass to both the superficial and the deep cervical glands; there are also a few small parotid lymph glands, which lie on the surface of the superior and inferior part of the parotid beneath the capsule. Some are said to be embedded in the substance of the parotid itself.

The **nerves** are derived (*a*) from the auriculo-temporal, great auricular, and facial, and (*b*) from the plexus caroticus externus. The fibres of the sympathetic are mainly vaso-constrictor.

The secretory fibres to the gland, arising in the brain-stem, pass out through the glosso-pharyngeal nerve, and pass from it through the lesser superficial petrosal nerve to the otic ganglion, and from that ganglion to the gland in the auriculo-temporal nerve.

Glandulæ Submaxillares.—The **submaxillary glands** are next in size to the parotid, and resemble them in their lobulation and colour. Each is placed largely in the submaxillary triangle under cover of the mandible (Fig. 875).

In each gland two portions may be recognised, a somewhat superficial larger part, the body, lying in the submaxillary triangle, and a smaller deep part, the deep process, which springs from the middle of the deep surface of the body.

The superficial part, like the parotid, presents a superficial convex surface, which projects below the mandible, in the submaxillary triangle, but it frequently extends beyond the limits of that space, and overlaps the digastric muscle.

This surface is covered by the deep cervical fascia and the platysma and is crossed superficially by the anterior facial vein.

The *body of the gland* is wedged upwards, between the medial surface of the mandible and the mylo-hyoid and hyo-glossus muscles. It thus presents two surfaces, a lateral, which is in contact with the submaxillary fossa of the mandible, and a medial, related to the mylo-hyoid, hyo-glossus, the posterior belly of the digastric, and the stylo-hyoid muscles.

The deep process passes around the posterior free margin of the mylo-hyoid muscle, and comes to lie between the mylo-hyoid and hyo-glossus muscles.

Embedded in the substance of the gland are found a few submaxillary lymph glands, which are of importance from the connexion they have with the lymph vessels of the lip and of a portion of the tongue.

The external maxillary artery lies embedded in a groove in the superior and posterior part of the gland.

The gland is enclosed in a delicate capsule of connective tissue derived from the deep cervical fascia.

In considering the relations of the gland, it is well to remark that there is in this region a three-sided space bounded laterally by the medial surface of the mandible below the mylo-hyoid line, medially and above by the mylo-hyoid muscle, and below by the skin and fascia passing from the margin of the jaw to the side of the neck. In this space the gland lies with lateral, medial, and inferior surfaces corresponding to the walls of the space.

The *posterior end* of the gland, which is its most bulky portion, either abuts against, or lies very close to, the sterno-mastoid, and is often overlapped by the inferior end of the parotid gland.

Ductus Submaxillaris.—The **submaxillary duct** (Wharton) leaves the deep surface of the gland about its middle, and runs forwards beneath the mylo-hyoid muscle, along the superior and medial aspect of the deep process of

the gland (Fig. 876). Pursuing its course forwards beneath the floor of the mouth, on the medial side of the sublingual gland, the duct crosses the hyo-glossus and the genio-glossus muscles, and finally opens on the floor of the mouth at the side of the frenulum linguæ, on the summit of a soft papilla **(caruncula sublingualis)** close to its fellow of the opposite side.

While running forward beneath the floor of the mouth the duct, which is about two inches long (50 mm.), is crossed by the lingual nerve near the anterior border of the hyo-glossus, that is opposite the 2nd molar tooth. The nerve passes from the posterior end of the mylo-hyoid ridge (against which it lies) forwards and medially in order to reach the inferior surface of the tongue, and it passes below the duct at the point indicated.

As in the case of the parotid duct, the calibre of the submaxillary duct is much greater than that of the orifice by which it opens; for this reason it likewise may be looked upon as forming, to some extent, a reservoir for the saliva secreted by the gland.

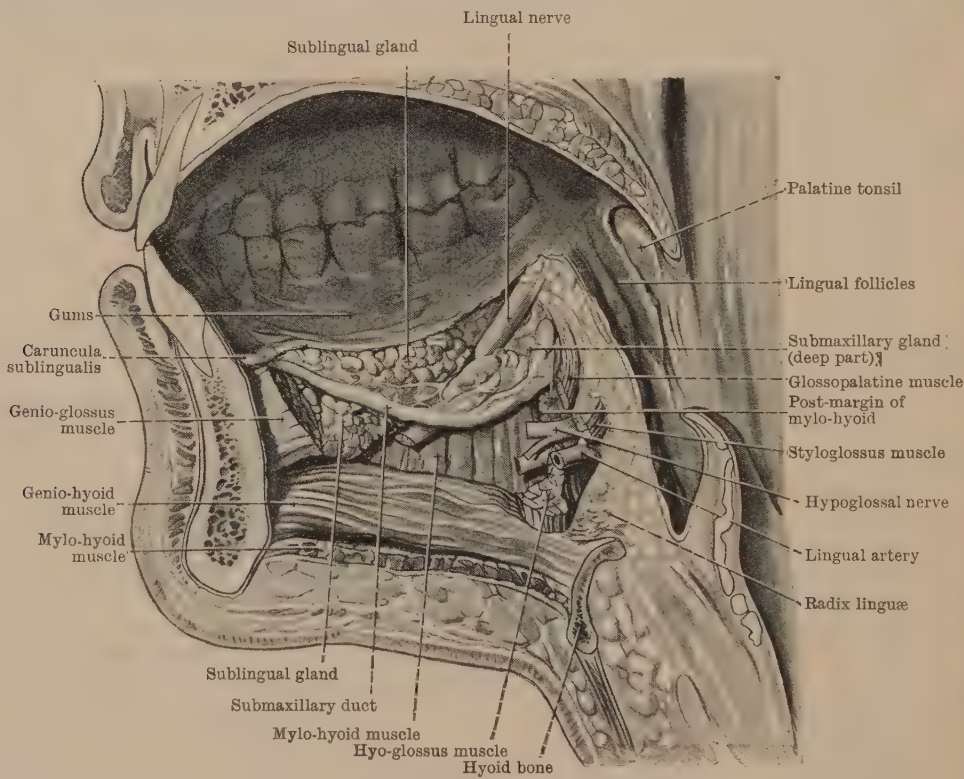

FIG. 876.—SIDE WALL AND FLOOR OF MOUTH, AFTER REMOVAL OF TONGUE AND MUCOUS MEMBRANE.

Vessels and Nerves.—The **arteries** come chiefly from the external maxillary artery and its submental branch: the **veins** accompany the arteries. The **nerves** are derived through the submaxillary ganglion (which lies above the deep process of the gland), from the chorda tympani and lingual, and from the sympathetic plexus around the external maxillary artery. The lymph vessels pass to the submaxillary lymph glands.

Glandulæ Sublinguales.—The **sublingual glands**, the smallest of the principal salivary glands, are situated more deeply than the others.

Each lies immediately below the mucous membrane of the floor of the mouth, in the interval between the sublingual fossa (on the inner surface of the mandible above the mylo-hyoid line) and the genio-glossus muscle, which passes from the mandible to the tongue. Below, it rests upon the deep surface of the mylo-hyoid muscle.

In shape it is almond-like, flattened from side to side, but is much wider (from above downwards) anteriorly than posteriorly. It is usually from $1\frac{1}{2}$ to $1\frac{3}{4}$ inches (37 to 45 mm.) in length, whilst its bulk is about equal to that of two or three almonds.

Its detailed relations are as follows:—Its *lateral surface* rests against the inner aspect

of the body of the mandible above the mylo-hyoid line. Its *medial surface* is in contact with the genio-glossus, stylo-glossus, and hyo-glossus muscles, as well as with the submaxillary duct, which runs forwards between the gland and the muscles. *Below*, it rests on the mylo-hyoid, and at its posterior part on the deep process of the submaxillary gland; whilst its *upper prominent border* is covered only by the mucous membrane of the mouth, and the plica sublingualis (Fig. 867). The anterior portion of the gland is much deeper and more bulky than the posterior half, and it meets its fellow in the median plane beneath the frenulum linguæ. The posterior extremity grows gradually more slender, but may extend to the posterior part of the mylo-hyoid ridge, where it lies above the deep process of the submaxillary gland.

The **ducts**, **ductus sublinguales minores** (O.T. **ducts of Rivinus**), are about twelve in number and of small size; they leave the superior part of the gland, and, after a short course, open on a series of papillæ, visible to the naked eye, which are placed along the summit of the plica sublingualis.

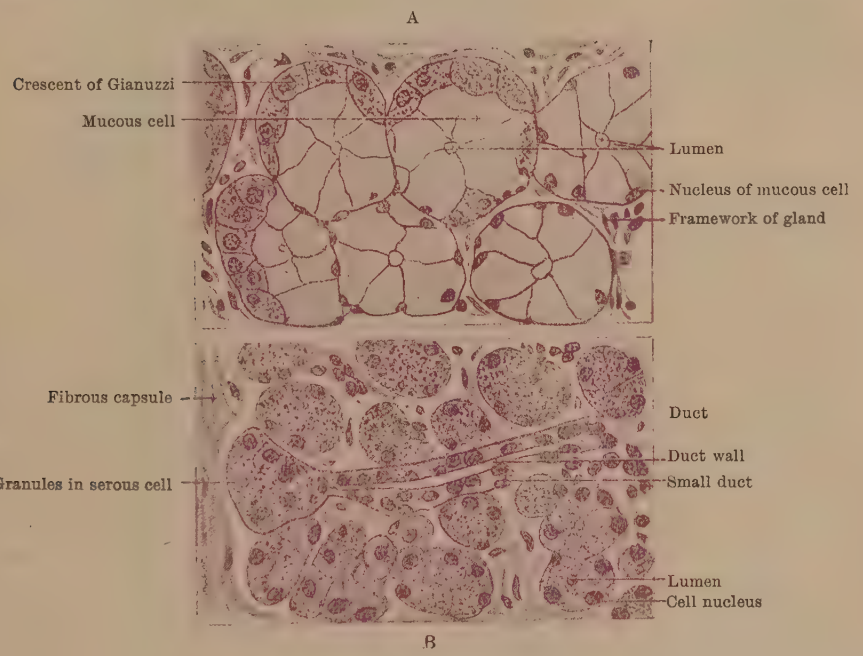

FIG. 877.

A. Section of human submaxillary gland × 400. B. Section of human parotid gland × 400.

The gland is not enclosed in a distinct capsule, thus differing from the parotid and submaxillary glands; but its numerous lobules, which are smaller than those of the glands just mentioned, are held together by fine connective tissue, loosely, but still in such a manner as to make one more or less consolidated mass out of what was, in the embryo, a number of separate glands.

As a rule all the ducts open separately on the summit of the plica sublingualis, and apparently none of them join the submaxillary duct. Frequently some of those from the anterior and more bulky part of the gland are larger than the others, but the presence of a large duct running alongside of the submaxillary duct, and opening with or beside it, **ductus sublingualis major** (**Bartolin**), is very rare, and must be considered as an exceptional condition in man, although normal in the ox, sheep, and goat. The same may also be said of ducts from the sublingual, which are described as opening into the submaxillary duct.

Vessels and Nerves.—The **arteries** are derived from the sublingual artery, a branch of the lingual, and from the submental, a branch of the external maxillary. The **nerves** come from the lingual, chorda tympani, and the external maxillary plexus, through a branch of the submaxillary ganglion which joins the lingual, and is conveyed by it to the gland. The secretory fibres run in the chorda tympani nerve, and thence through the submaxillary ganglion to the gland.

The **glandula lingualis anterior** (Blandini, Nuhni) has been described with the tongue.

Structure of the Salivary Glands (Fig. 877).—Each of the principal salivary glands consists of a number of lobules, loosely united together by connective tissue. From each of them

one or more ducts emerge. Each duct when traced onwards divides into branches, which terminate in a group of saccular or tubular alveoli.

The epithelium lining the ducts is columnar in character, but becomes flattened at the junction with the alveoli.

The epithelium lining the alveoli shows different characters in different glands. In the parotid, and the small salivary glands of the vallate papillæ in which the secretion is watery or albuminous, the cells are uniform in character, and of small size. When the gland is at rest, the cells are filled with small granules, which when the secretion is poured out are transformed into the gland ferment (ptyalin). After secretion, only the deeper parts of the cells show the presence of granules. The nuclei are rounded, and lie near the centre of the cells. In the sublingual, labial, buccal, and other glands of the mouth and palate the secretion is of a mucous character and the cells are larger, and the nuclei are placed deeply. The cells appear clear and swollen unless special methods of preparation are employed. In such cases, *e.g.*, when examined in serum, the cells are seen to contain large and distinct granules of mucigen which in secretion are transformed into mucus.

In the submaxillary gland and the anterior lingual gland both varieties of cells are present. In these cases, the larger clear mucus cells line the cavity of the alveolus, and the smaller granular serous cells are arranged upon the basement membrane, deep to the former cells, in crescentic masses, termed the crescents or demilunes of Gianuzzi. They communicate with the cavity of the alveolus by small channels between adjacent mucous cells.

After secretion, the mucus cells become smaller, and stain more deeply than when loaded with mucigen before secretion.

PHARYNX.

The **pharynx** lies posterior to and communicates with the mouth, the larynx, and the nasal cavities, and is continuous inferiorly with the superior end of the œsophagus or gullet (Fig. 878).

It extends from the base of the skull, above, to the level of the sixth cervical vertebra (Fig. 878) and the lower border of the cricoid cartilage, below.

Its total length varies from 5 to 5½ inches (12·5 to 14·0 cm.).

The inferior portion alone, opposite and inferior to the opening of the mouth, is functionally a part of the alimentary canal, for the portion above the level of the soft palate is used for respiration only. It is, however, convenient to study the structure and relations of the whole of the pharynx at once.

Structurally the pharynx is a fibro-muscular bag, lined with mucous membrane, of conical form, wide above and narrow below. The wall of the superior part of the pharynx is firmly attached to the base of the skull, especially around the orifice of the choanæ, and hence in this superior portion there is a permanent cavity containing air.

The lower portion gradually assumes a more tubular form, and the anterior and posterior walls approach one another, so that below the level of the opening of the larynx they are in contact with one another, and the cavity is reduced to a slit, except during the passage of food.

Dimensions of the Pharynx.—From the highest part of the roof, to the superior surface of the soft palate at its junction with the hard palate, measures about 1¼ inches, or 3 cm. The vertical extent of the oral part of the pharynx is about 2¼ inches, or 6 cm., and that of the laryngeal part is about 2¾ inches, or 7 cm.

The inferior end of the pharynx is usually about 5½ to 6½ inches from the margins of the incisor teeth, in a line passing through the cavities of the mouth and of the oral and laryngeal parts of the pharynx.

The other diameters are as follows: the antero-posterior diameter (depth) of the superior segment (nasal portion), from the posterior margin of the septum of the nose at its inferior part horizontally backwards, measures 15 to 18 mm., and that of the middle segment, from the glosso-palatine arches to the posterior wall, about 10 mm.

The transverse width of the pharynx also varies considerably. Immediately below the base of the skull the cavity is wide, as there is on each side a deep recess, and it measures 45 mm., or nearly 2 inches.

Opposite the middle of the soft palate the cavity narrows, and measures transversely 25 mm., or 1 inch.

It again widens out below this level, and expands to a width of 35 mm., opposite the inferior margin of the laryngeal opening, where on each side there is a wide recess, called the piriform recess.

Cavum Pharyngis.—The **cavity of the pharynx** is partially intersected by the soft palate, which cuts into the cavity of the pharynx (Fig. 878), and incompletely divides it into two, namely, an upper part, **pars nasalis**, and a lower part or

pharynx proper. This lower portion is further subdivided into the **pars oralis**, lying behind the mouth and tongue, and the **pars laryngea**, behind the larynx.

The aperture left between the margin of the soft palate and the posterior wall of the pharynx, by which the nasal part of the pharynx communicates with the inferior divisions of the cavity, is called the **isthmus pharyngonasalis.**

The pharynx presents *seven openings* by which it communicates with neighbouring cavities (Fig. 878). These are the two **choanæ** (O.T. **posterior nares**)

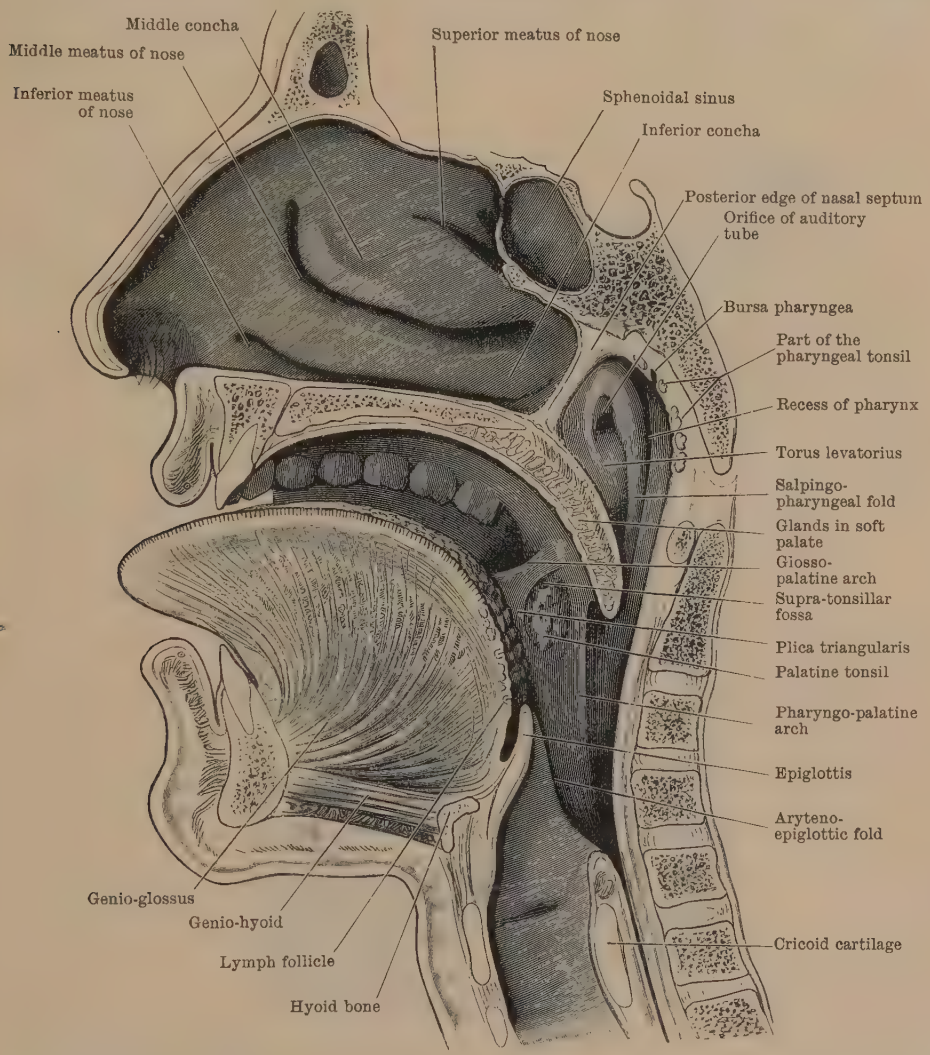

Fig. 878.—Sagittal Section through Mouth, Tongue, Larynx, Pharynx, and Nasal Cavity.

The section was slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below, hence the apparently low position of the inferior concha.

on the anterior wall of the pars nasalis, and the two **tubæ auditivæ** on its side walls; the isthmus of the fauces, leading into the mouth from the oral part; the orifice of the larynx on the anterior wall of the laryngeal part of the cavity; and finally, the opening of the œsophagus at its inferior end.

Pars Nasalis (Figs. 851 and 878).—Although morphologically and developmentally this is a portion of the true pharynx, it is functionally an annexe to the respiratory portion of the nasal cavities, and both anatomically and functionally it is distinctly marked off from the digestive tube. It differs from the rest of the pharynx in that its cavity remains, under all conditions, a distinct open

chamber incapable of obliteration, owing to the fact that all its walls, with the single exception of the floor, are practically immovable.

The cavity of the pars nasalis is irregular in shape, and is enclosed by *six walls*—namely, anterior and posterior, right and left, a floor and a roof or vault.

These walls all merge into one another, and the lines of separation between them are arbitrary. Through the *anterior wall*, which slopes upwards and backwards, open the **choanæ**, separated from each other by the nasal septum. The margins of the choanæ form the line of separation between the pars nasalis and the cavity of the nose. This separation is occasionally marked by a furrow or fold on the side wall, called the naso-pharyngeal furrow.

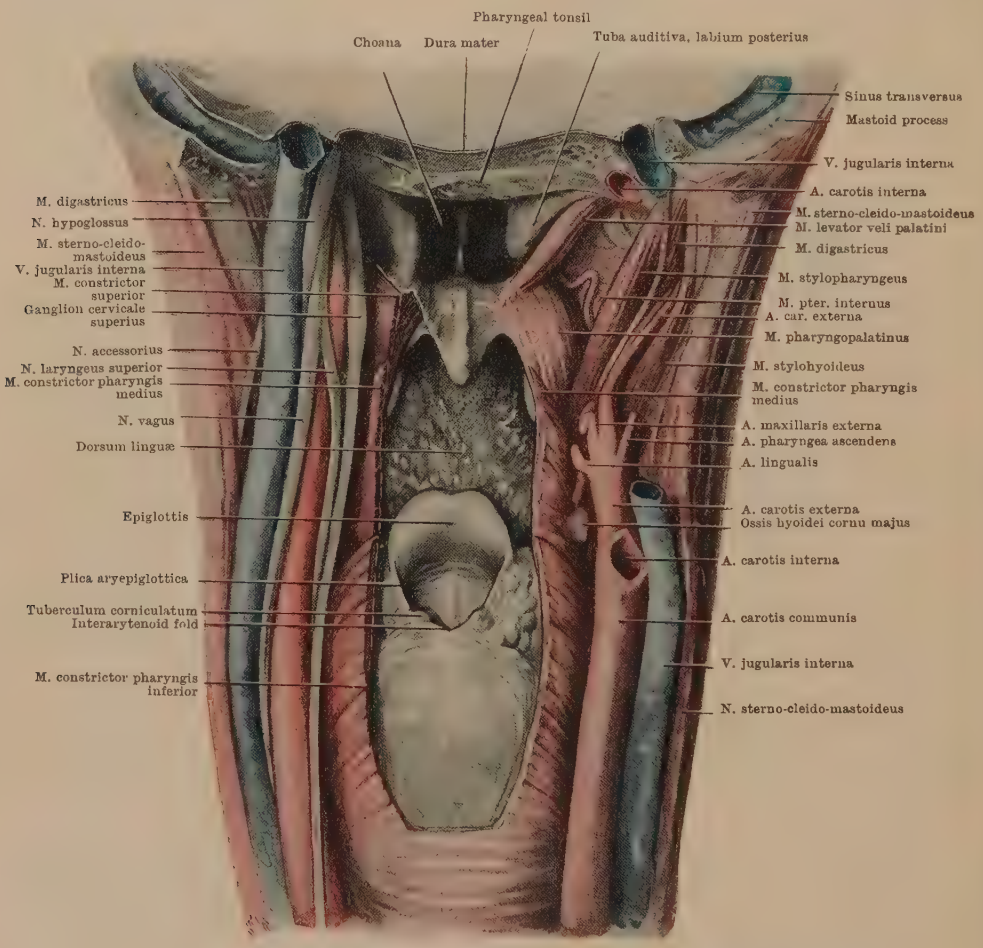

FIG. 879.—INTERIOR OF PHARYNX AND STRUCTURES IN RELATION TO ITS SIDE WALLS, VIEWED FROM BEHIND.

The *posterior wall* is nearly vertical; it corresponds in extent to the basi-occipital bone and the upper six cervical vertebræ.

The *roof* lies under the body of the sphenoid, and on each side it extends downwards to the superior margin of the orifice of the auditory tube. It slopes from in front downwards and backwards to meet the posterior wall at the junction of the basilar part of the occipital and sphenoid bones.

The lateral walls are occupied by the pharyngeal opening of the auditory tube, and posterior to them, by a vertical slit-like depression leading into a recess, called the **recessus pharyngeus** (Rosenmülleri).

The *floor* is formed by the upper surface of the soft palate.

In the posterior part of the roof, and superior part of the posterior wall, there is a considerable accumulation of lymph tissue, known as the **pharyngeal tonsil.** It

is most distinct in the child, and becomes indistinct, or entirely disappears, in adult life. It extends from the body of the sphenoid down as far as to the margin of the occipital bone, and, laterally, as far as to the superior part of the side wall. The mucous membrane which covers it is thickened and thrown into transverse folds.

A similar collection of lymphoid tissue, a lateral prolongation of the pharyngeal tonsil, lies behind the mouth of the auditory tube, and it is known as the "*tubal tonsil*."

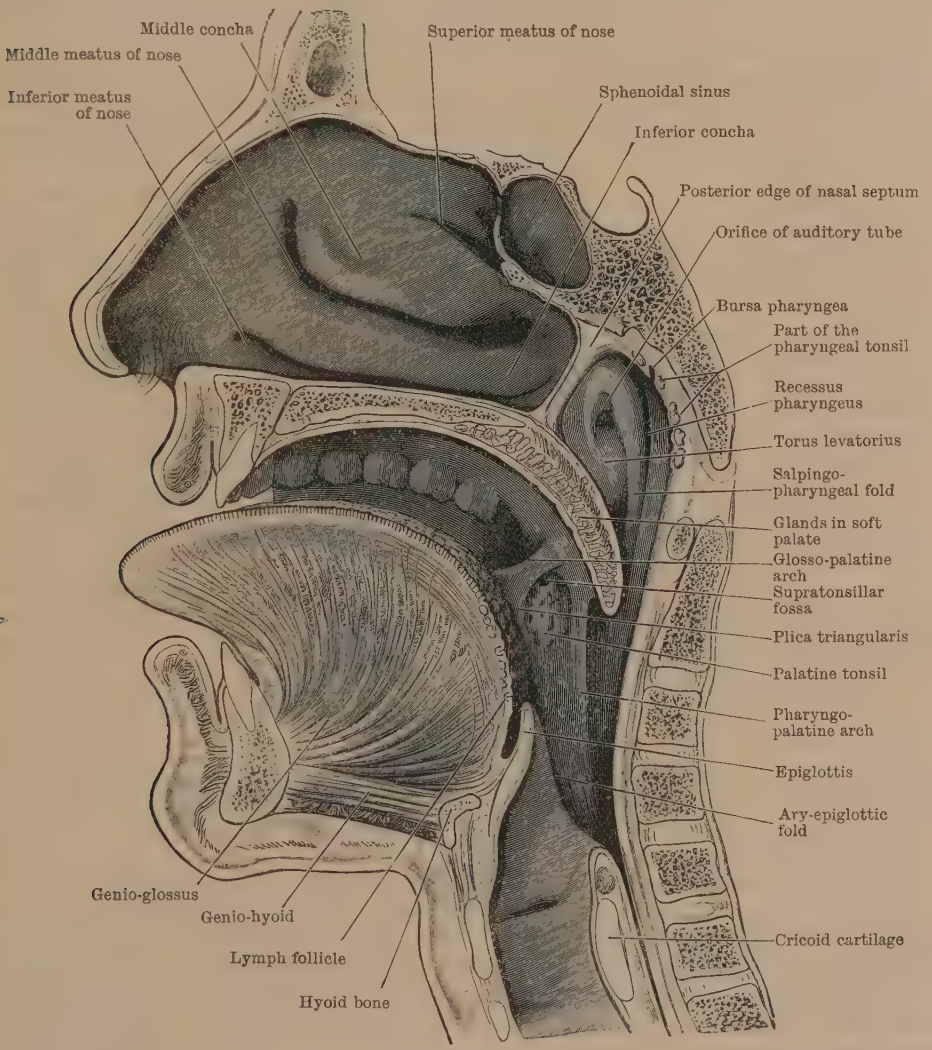

FIG. 880.—SAGITTAL SECTION THROUGH MOUTH, TONGUE, LARYNX, PHARYNX, AND NASAL CAVITY.

The section is slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below, hence, in part, the low position of the inferior concha.

In connexion with the inferior part of the pharyngeal tonsil, there is found, constantly in the child and occasionally in the adult, a small median recess which runs upwards and backwards in the wall of the pharynx for some distance, and is known as the **bursa pharyngea** (Fig. 880).

Enlargement of the lymph tissue here occurs frequently in children, and the swollen lymph nodules are known as adenoids. The enlargement may become so great as to fill up a great part of the cavity of the nasal part of the pharynx.

Embedded in the tissue of the roof of the pharynx, near the orifice of the cranio-pharyngeal canal, is a nodule of tissue which in structure resembles the anterior lobe of the hypophysis cerebri. It is termed the **pharyngeal hypophysis**, and is composed of strands of epithelial cells,

some follicles containing colloid material, and a few chromatin cells. Its size and its exact position are variable.

Ostium Pharyngeum Tubæ Auditivæ.—The **pharyngeal orifice** of the **auditory tube** is oval or triangular, and funnel-like in appearance (Fig. 880). It is bounded superiorly and posteriorly by a prominent rounded ridge, the **torus tubarius** (O.T. **Eustachian cushion**), formed by the cartilage which surrounds the auditory tube superiorly and posteriorly. The prominence of the posterior margin (labium posterius) as contrasted with the anterior margin (labium anterius) of the orifice, and the direction of the tube itself, which runs posteriorly and laterally (from the pharynx to the tympanum), greatly facilitate the introduction of a Eustachian catheter.

The orifice is situated on the side wall of the pars nasalis, a short distance (about $\frac{1}{3}$ to $\frac{1}{2}$ inch) behind the posterior end of the inferior concha, and immediately above the level of the hard palate (Figs. 851 and 880).

A slight ridge of the mucous membrane, the **plica salpingopharyngea**, descends from the inferior end of the torus tubarius on the side wall of the pharynx. Another less-developed ridge, the **plica salpingopalatina**, passes from the anterior border of the ostium pharyngeum downwards and forwards to join the palate. In front of the latter lies the indistinct groove, the **naso-pharyngeal groove**, which indicates the separation of the nasal cavity from the nasal part of the pharynx.

The levator veli palatini in descending runs parallel to the tuba auditiva, and along its lower border. As it enters the palate, it produces, particularly when in a state of contraction, an elevation just below the pharyngeal orifice of the tube, known as the **torus levatorius** (Fig. 880), which in its upper portion abuts against the lower part of the orifice, and forms its base when that opening assumes its usual triangular shape.

Immediately posterior to each osteum pharyngeum is the **recessus pharyngeus** (O.T. **lateral recess of the pharynx** or **fossa of Rosenmüller**), a nearly vertical depression of considerable depth (Fig. 880).

The pharyngeal recesses project laterally over the superior margin of the superior constrictor, below the petrous portion of the temporal bone, and correspond in position to the sinus of Morgagni on each side (cf. description of pharyngeal wall, p. 1142).

Pars Oralis.—The oral part of the pharynx lies behind the mouth, between the soft palate above and the superior aperture of the larynx below. On its *anterior aspect* is the isthmus of the fauces, leading into the mouth. Below this the vertical pharyngeal portion of the tongue forms the anterior wall. Its *side wall* (Fig. 880) presents a triangular area, **sinus tonsillaris**, occupied in the greater part of its extent by the **tonsil**. Above the tonsil there is a depression, the **fossa supratonsillaris** (Fig. 880).

The **arcus pharyngopalatinus** (O.T. **posterior pillar of the fauces**) is a fold of mucous membrane, containing in its interior the pharyngopalatinus muscle. It springs from the posterior edge of the soft palate, and, passing downwards and slightly backwards, ends inferiorly on the side wall of the pharynx (Fig. 880). The two pharyngo-palatine arches form the right and left boundaries of the pharyngo-nasal isthmus, and the orifice can be modified in size by the contraction of the pharyngo-palatine muscles.

The **arcus glossopalatinus** is described on p. 1109.

By the contraction of the pharyngo-palatine muscles, which are enclosed within the pharyngo-palatine arches, the sides of the isthmus can be approximated, like two curtains, and its size correspondingly diminished. When, at the same time, the uvula and soft palate are elevated, and the whole pharynx in this region is narrowed by the contraction of the superior constrictor, the aperture can be completely closed, and the oral separated from the nasal part of the pharynx, as in the acts of swallowing and vomiting.

Tonsillæ Palatinæ.—The **palatine tonsils** are two large, oval masses of lymph tissue which are embedded in the side walls of the oral part of the pharynx in the lower part of a triangular recess, the sinus tonsillaris.

The tonsillar sinus is bounded anteriorly by the glosso-palatine arch,

posteriorly it is bounded by the more vertical pharyngo-palatine arch; the inferior boundary is formed by the margin of the tongue, while the narrow apex above passes up to the side of the soft palate.

From the posterior surface of the glosso-palatine arch a thin triangular fold of mucous membrane, called the **plica triangularis**, passes backwards. Its base corresponds to the glosso-palatine arch, its superior border is free, and passes downwards and backwards, frequently overlapping the tonsil. Its lower border is attached to the side of the tongue. It covers, medially, the inferior part of the tonsillar fossa.

The palatine tonsil presents very different forms in different individuals.

It may project from the fossa into the cavity of the pharynx, or it may be flat and limited to the tonsillar fossa. In some cases the plica triangularis is fused with the free surface of the tonsil, and the lymph tissue may in some cases be developed on the medial surface of that plica.

The palatine tonsils are oval in shape, with the long axes directed vertically,

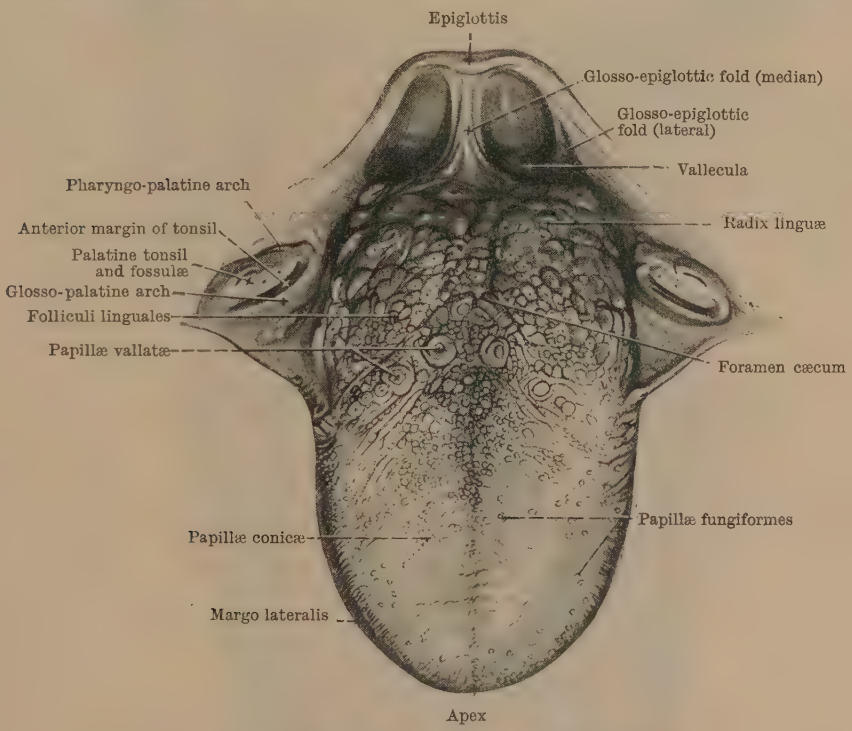

FIG. 881.—DORSUM OF TONGUE AND PALATINE TONSILS.

and each presents a medial and a lateral surface, and a superior and inferior pole, and an anterior and posterior margin.

The medial surface is prominent and free, studded with small pit-like depressions called the fossulæ or crypts of the tonsil.

The lateral, or attached surface, is enclosed in a distinct fibrous capsule, connected with the pharyngo-basilar fascia, and this capsule separates the tonsil from the superior constrictor muscle of the pharynx.

The superior pole is rounded and blunt, and presents numerous fossulæ. The inferior pole projects downwards towards the tongue. The anterior margin looks towards the glosso-palatine arch, and is often overlapped by the plica triangularis; the posterior margin is directed towards the pharyngo-palatine arch.

The supra-tonsillar fossa is a recess of considerable size, which extends into the soft palate, and opens by a narrow orifice into the upper part of the tonsillar sinus (Figs. 880 and 881).

Relations of the Tonsil.—The lateral relations of the tonsil consist of the fibrous capsule and the superior constrictor muscle. Lateral to the pharyngeal wall lies the internal pterygoid muscle, and behind it a region filled with connective tissue, containing blood-vessels and nerves.

The nearest and most important vessel is the external maxillary artery, which, especially if tortuous, has a very close relation to the pharyngeal wall at this level.

The ascending palatine and tonsillar branches of the artery are also in close relation.

The internal carotid artery and internal jugular vein lie considerably further back ($\frac{3}{4}$ to 1 inch) and to the lateral side, and the external carotid artery is still more lateral.

The ascending pharyngeal artery is well behind the tonsil.

The size of the palatine tonsils is extremely variable, but as a rule, in early life, they measure something under 1 inch (20 to 22 mm.) from above downwards, about $\frac{3}{4}$ inch (18 to 20 mm.) antero-posteriorly, and $\frac{1}{2}$ inch (12 to 15 mm.) medio-laterally.

The **arteries** of the palatine tonsil are derived from the ascending palatine and tonsillar

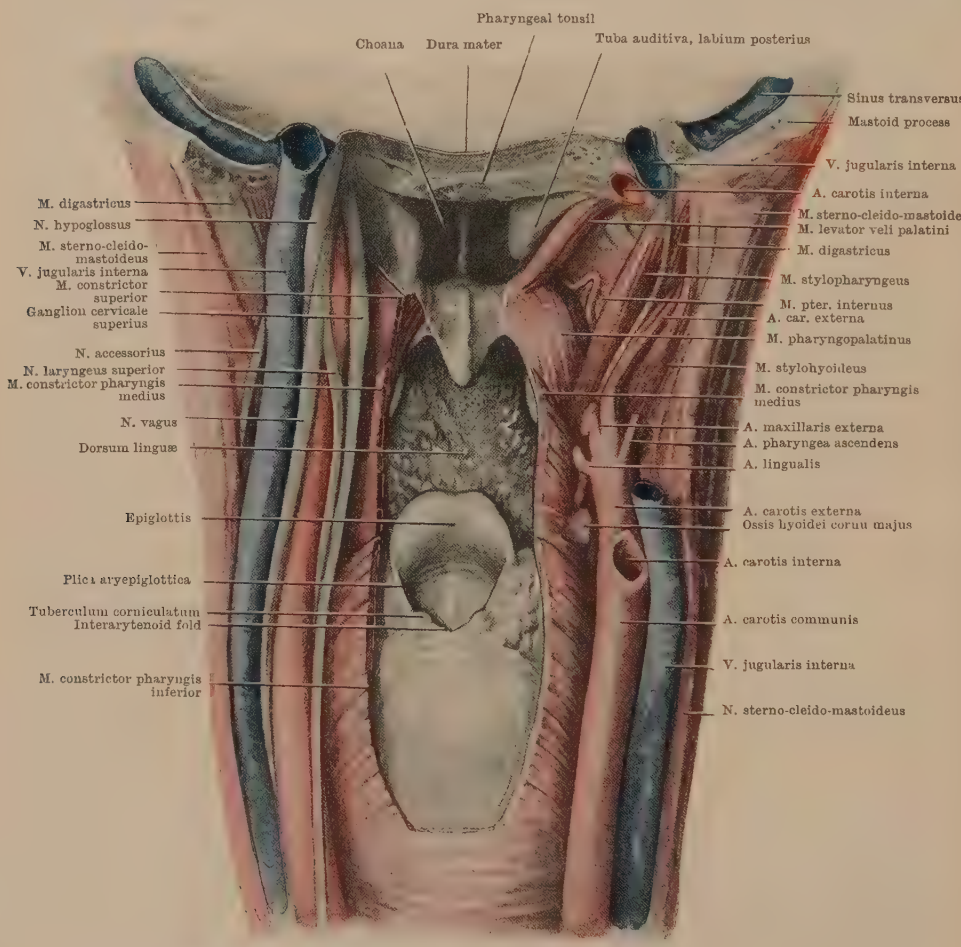

FIG. 882.—INTERIOR OF PHARYNX AND STRUCTURES IN RELATION TO ITS SIDE WALLS, VIEWED FROM BEHIND.

branches of the external maxillary artery, the ascending pharyngeal branch of the external carotid, and the dorsalis linguæ of the lingual. The **veins** pass to the tonsillar plexus, on the lateral side of the tonsil, which is an offshoot of the pharyngeal venous plexus.

Nerves.—The palatine tonsil receives a special branch from the glosso-pharyngeal; this unites with branches from the pharyngeal plexus to form a small **plexus tonsillaris** which supplies the organ.

The **lymph vessels** are extremely numerous. They begin in a plexus which surrounds each follicle, whence vessels pass to the lateral surface of the tonsil. Thence they pass through the wall of the pharynx, and pass to the deep cervical glands in the neighbourhood of the greater cornu of the hyoid bone, behind and inferior to the angle of the mandible.

Structure of the Palatine Tonsils.—Each palatine tonsil is composed of masses of small rounded lymph cells with a delicate connective tissue reticulum. These resemble in structure the follicli linguales, *q.v.*

Upon its medial surface it is covered with epithelium, continuous with the epithelium covering

the adjacent parts of the wall of the pharynx. This surface is very irregular, and on section crypts, termed fossulæ tonsillares, are seen to be formed by deep infoldings of the epithelial wall. On its lateral surface, the lymph tissue is invested by a connective tissue capsule.

Pars Laryngea.—The **laryngeal part** of the pharyngeal cavity lies posterior to the larynx (Fig. 880). It is wide above, but at the level of the cricoid cartilage it narrows rapidly and passes down to join the œsophagus.

The *anterior wall* of the laryngeal portion of the pharynx is formed in its whole extent by the posterior surface of the larynx, of which the following parts are seen from the pharyngeal cavity (Fig. 882): The epiglottis above; below this the superior aperture of the larynx, bounded at the sides by the ary-epiglottic folds;

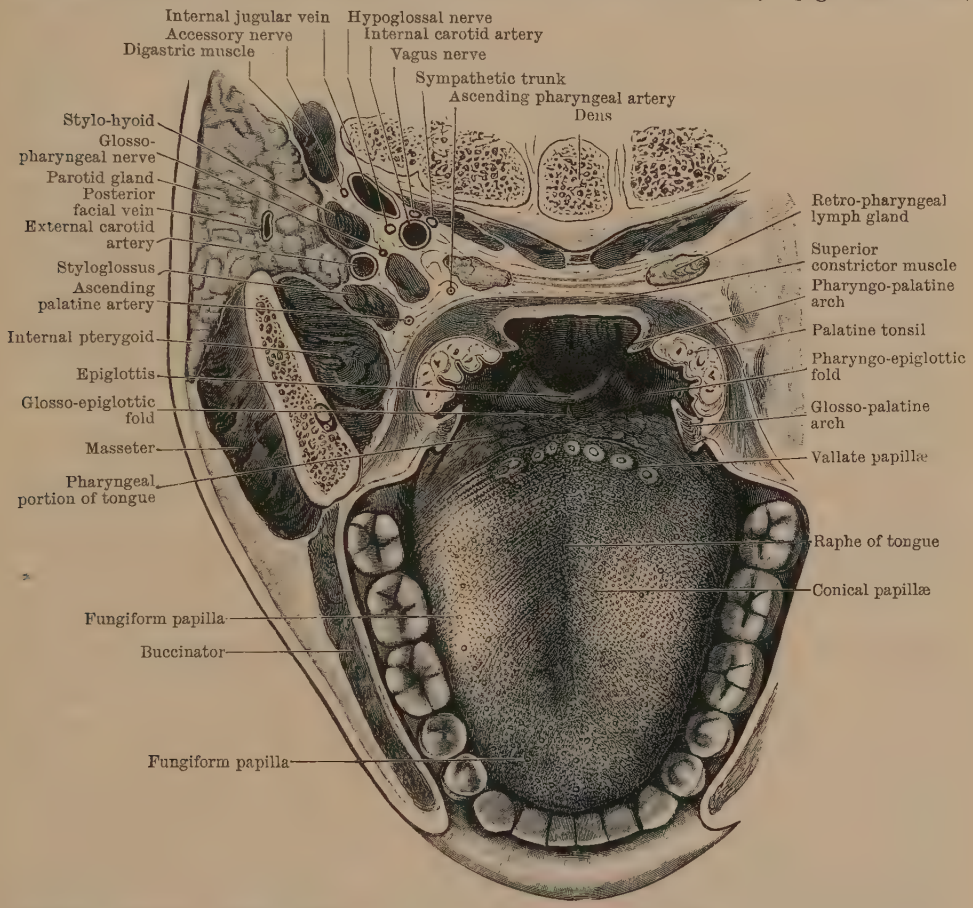

FIG. 883.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE PALATINE TONSILS.

The stylopharyngeus, which is shown immediately to the medial side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines.

lateral to these folds is seen, on each side, a deep recess, the **recessus piriformis** (Fig. 825). Lower down still, the muscles and mucous membrane which cover the posterior surfaces of the arytenoid and cricoid cartilages are distinguishable.

The **recessus piriformis** is a depression on each side between the ary-epiglottic fold and the lamina of the thyreoid cartilage. When viewed from above, as in laryngoscopic examinations, it appears of a piriform shape, the wider end being directed upwards and forwards. When viewed from behind, the recess is boat-shaped and elongated in the vertical direction. Its side wall is formed by the thyreoid cartilage and thyreo-hyoid membrane, covered with mucous membrane; its medial wall is formed by the ary-epiglottic fold, and slightly, below, by the superior part of the cricoid cartilage.

Relations of the Pharynx.—In considering the relations of the pharynx, it is at once evident that these are very different in the superior and inferior portions.

1. Throughout its whole extent it lies anterior to the cervical region of the vertebral column, and is separated from the bodies of the vertebræ and the intervertebral fibro-cartilages by the loose areolar tissue of the prevertebral or retro-pharyngeal space, posterior to which lie the anterior longitudinal ligament of the vertebral column, and the longus capitis and longus colli muscles.

2. **In the neck,** on each side, it is in contact with the superior part of the thyreoid gland, the carotid sheath, and especially the common and external carotid arteries and, more posteriorly, the internal carotids.

The branches arising from the inferior part of the external carotid are also in close relation to the pharyngeal wall, viz., the superior thyreoid and lingual arteries in the lower part, while the external maxillary artery, as it passes under the digastric and stylo-hyoid muscles, comes into contact with the superior constrictor; and the ascending pharyngeal artery runs upwards by the side of the pharyngeal wall.

3. The relations of the **cranial portion** are more complex, but are of great importance. Reference to Fig. 883 will help to elucidate them. At the upper part, the wall of the pharynx is related to the internal pterygoid muscles, separated from them by the levator and tensor veli palatini muscles. As each internal pterygoid passes posteriorly and downwards to its insertion, it diverges away from the pharynx, and a triangular space is left between its medial surface and the wall of the pharynx. The styloid process, and the muscles which arise from it, project downwards into this space, and lying beside them are numerous vessels and some nerves. Thus, the stylo-glossus and stylo-pharyngeus come into contact with the side wall, and, with the stylo-pharyngeus, the glossopharyngeal nerve. The ascending palatine and tonsillar branches of the external maxillary artery ascend in close relation to the pharyngeal wall.

The internal carotid artery lies rather further back, with the vagus, accessory and hypoglossal nerves.

The external carotid lies more superficially, and is here separated by a considerable interval from the pharyngeal wall.

Lastly, a process of the parotid gland may insert itself on the medial aspect of the internal pterygoid, and come into contact with the pharynx.

The pharyngeal plexus of nerves lies in contact with the side wall.

Structure of the Pharyngeal Wall.—The wall of the pharynx is firmly fixed above to the base of the skull, but below that level it is not attached firmly to any surrounding structures, except to the hyoid bone and the skeleton of the larynx.

The wall is composed of a strong fibrous membrane, called the **fascia pharyngo-basilaris** (O.T. **pharyngeal aponeurosis**), lined internally by mucous membrane, and covered incompletely on its outer surface by a series of three overlapping muscles, the constrictor muscles of the pharynx.

These muscles are themselves covered externally by a thin layer of fibrous tissue or fascia, which passes forwards, at its superior part, on to the surface of the buccinator muscle, and is called the **fascia buccopharyngea.**

External to this fascia the wall of the pharynx is in contact with loose cellular tissue by which it is connected to and separated from adjacent structures.

With the wall of the pharynx are associated several accessory muscles, viz., the muscles of the soft palate and the stylopharyngeus and pharyngo-palatine muscles, which blend with the wall but are also attached to the larynx (see p. 465).

The fibrous aponeurosis which forms the principal constituent of the pharyngeal wall is firmly attached (round the margins of the openings into the pharynx) to other structures as follows:—

Above, it blends with the periosteum covering the basilar portion of the occipital bone in front of the pharyngeal tubercle, and on each side it extends out to the angular spine of the sphenoid and the inferior surface of the pyramid of the temporal bone, in front of the carotid foramen, and lateral to the opening of the auditory tube.

On each side it is attached to the medial pterygoid lamina, the pterygo-mandibular raphe, and the mylo-hyoid ridge, and is eventually lost on the side of the tongue.

The fascia pharyngobasilaris is particularly strong in the superior part, where there is an area on each side which is not covered by the superior constrictor muscle. This area forms the sinus of Morgagni, and here the tensor and levator veli palatini muscles pass through the wall.

Mucous Membrane of the Pharynx.—The mucous membrane of the pharynx consists, in the lower part, of a stratified squamous epithelium, while in the upper or nasal portion it is, in part, composed of ciliated epithelium. In the superior part of the pharynx and in the side wall, there are found large masses of lymph tissue, constituting the pharyngeal tonsil in the roof, and the palatine tonsil on each side. The same tissue is found in considerable amount in the pharyngeal recess and on the pharyngeal portion of the dorsum of the tongue.

There are also numerous racemose glands, of the mucous type, in the walls of the pars nasalis, and in the soft palate, and in the ary-epiglottic folds.

Pharyngeal Muscles.—For the details of the attachment and relations of these muscles, see pp. 464-466.

External to the pharyngeal muscles lies the fascia buccopharyngea.

The fascia pharyngobasilaris, which is thick above and thin below, and the fascia buccopharyngea, which is thin above and stouter below, are practically blended into one layer above, near the base of the skull, where the muscular coat is absent. Lower down they are separated by the constrictors, and become two distinct sheets. They are strengthened in the median plane posteriorly by a fibrous band descending from the pharyngeal tubercle.

Vessels and Nerves of the Pharynx.—The **arteries** of the pharynx are derived from—1, the ascending pharyngeal; 2, the ascending palatine branch of the external maxillary; 3, the descending palatine from the internal maxillary, with a few twigs from the dorsalis linguæ, tonsillar (of external maxillary), the artery of the pterygoid canal, and the pharyngeal branch of the internal maxillary. The **veins** go to the pharyngeal venous plexus, which is found between the constrictors and the bucco-pharyngeal fascia. The plexus communicates with the pterygoid plexus above and with the internal jugular or common facial vein below.

The **lymph vessels** of the pharynx pass chiefly to the superior set of deep cervical glands. Those from the superior part of the posterior wall join a few retro-pharyngeal glands which are found on each side between the pharynx and the rectus capitis anterior muscle. These latter glands, which are large in the child, small in the adult, but apparently always present (Fig. 883), are of considerable clinical interest, as they often form the starting-point of post-pharyngeal abscess. For fuller details see section on Lymph Glands.

The **nerves** of the pharynx, both motor and sensory, are derived chiefly from the pharyngeal plexus, which is formed by branches of the vagus, glosso-pharyngeal, and sympathetic. The soft palate and the neighbourhood of the palatine tonsil are supplied by the palatine branches of the spheno-palatine ganglion. The tonsil receives a branch from the glosso-pharyngeal direct. The vault of the pharynx, and the region around the orifice of the tuba auditiva, as well as the orifice itself, are supplied by branches from the spheno-palatine ganglion. Finally, the internal laryngeal nerve supplies the mucous membrane of the back of the larynx, where it forms the anterior wall of the laryngeal portion of the pharynx.

ŒSOPHAGUS.

The **œsophagus** or **gullet** is, with the exception of the pylorus, the narrowest, and at the same time one of the most muscular parts of the whole alimentary tube.

It extends from the termination of the pharynx, at the inferior border of the cricoid cartilage and opposite the sixth cervical vertebra, to the cardiac orifice of the stomach, opposite the eleventh thoracic vertebra. Between those two points it traverses the inferior part of the neck, the whole length of the thorax, and, having pierced the diaphragm, it enters the abdomen, and immediately afterwards joins the stomach. In its course it does not adhere to the median plane of the body, but twice leaves it, and curves to the left. In the inferior part of the neck and the superior part of the thorax, the œsophagus projects to the left beyond the margin of the trachea to the extent of $\frac{1}{6}$ or $\frac{1}{4}$ inch (4 to 6 mm.). It returns to the median plane at the level of the fourth thoracic vertebra, posterior to the aortic arch. Lower down, posterior to the pericardium, at the level of the seventh cervical vertebra, it again passes to the left, and at the same time forwards, in order to reach the œsophageal opening in the diaphragm, and it maintains this direction until the stomach is reached. It crosses anterior to the aorta at the level of the eighth thoracic vertebra, and traverses the diaphragm at the level of the tenth.

In addition to the curvatures just described, it is also curved in the antero-posterior direction, in correspondence with the form of the vertebral column, upon which it, in great part, lies.

In *length* it usually measures from ten inches (25 cm.) to twelve inches (30 cm.).

Its *breadth*, where the tube is widest, varies between half an inch (13 mm.) in the empty contracted condition and an inch or more (25 to 30 mm.) in the fully distended state.

In cross sections (Fig. 885) the œsophagus appears either as a flattened tube with a

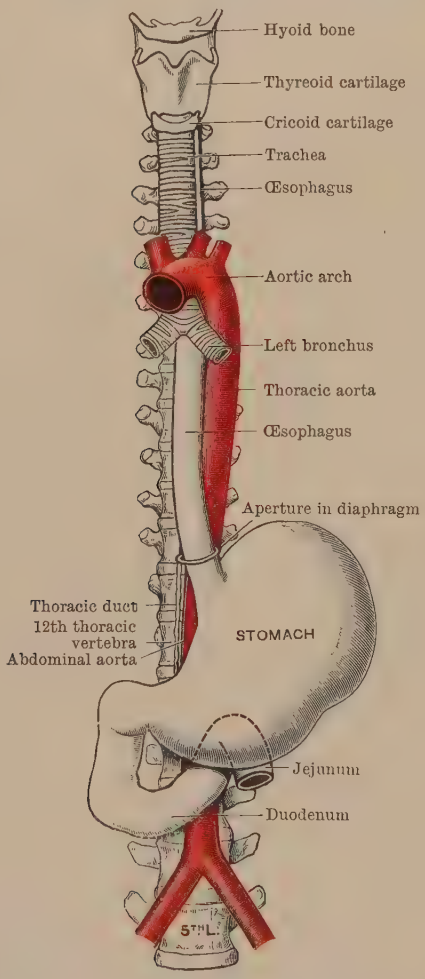

FIG. 884.—DIAGRAM TO SHOW THE COURSE OF THE ŒSOPHAGUS.

transverse slit-like cavity, or as an oval or rounded canal with a stellate lumen. The former condition is more common in the neck, owing to the pressure of the trachea, and the latter in the thorax.

When exposed in the ordinary post-mortem examination soon after death, it has rather the appearance of a solid muscular rod or band than of a hollow tube.

The œsophagus presents three distinct *constrictions*, one situated at its beginning, another at the point where it is crossed by

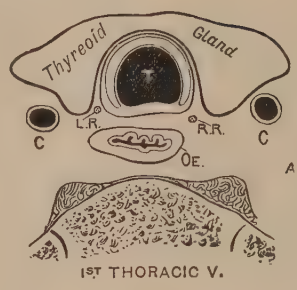

Fig. A is at level of the superior part 1st thoracic vertebra, and shows the chief relations of the œsophagus in the neck and also its divergence to the left.

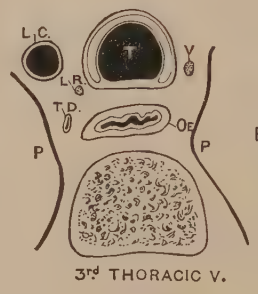

Fig. B, at the 3rd thoracic vertebra, shows the thoracic duct lying on left side of the œsophagus.

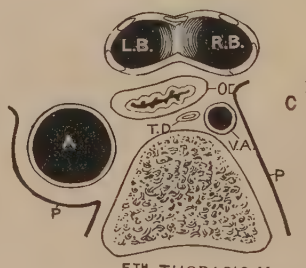

In Fig. C, at the level of the 5th thoracic vertebra, the left bronchus is seen in relation to the anterior surface of the œsophagus.

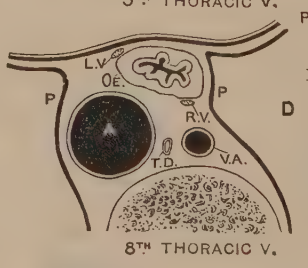

Fig. D is at the level of the 8th thoracic vertebra, and shows the pericardium lying on the anterior surface of the œsophagus.

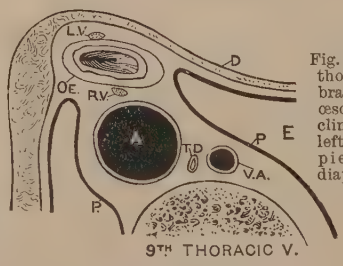

Fig. E, at the 9th thoracic vertebra, shows the œsophagus inclining to the left just before piercing the diaphragm.

FIG. 885.—TRACINGS FROM FROZEN SECTIONS TO SHOW THE RELATIONS OF THE ŒSOPHAGUS at the levels of the 1st, 3rd, 5th, 8th, and 9th thoracic vertebræ, respectively.

A, Aorta; C, Common carotid artery; D, Diaphragm; L.B, Left bronchus; L.C, Left subclavian artery; L.R, Left recurrent nerve; L.V, Left vagus; OE, Œsophagus; P, Pleura; Pc, Pericardium; R.B, Right bronchus; R.R, Right recurrent nerve; R.V, Right vagus; T, Trachea; T.D, Thoracic duct; V.A, Vena azygos.

the left bronchus, and the third where it passes through the diaphragm. The two upper constrictions are of the same size, and will admit without injury an instrument with a maximum diameter of $\frac{4}{5}$ inch (20 mm.). At each of these points the tube is flattened from before backwards.

The distance from the upper incisors to the beginning of the œsophagus averages about 6 inches (15 cm.).

The size at the two constrictions, when the tube is fully distended, is 23 mm. transversely, and 17 mm. antero-posteriorly. The other parts vary in diameter between 26 and 30 mm. (Jonnesco).

In its first curvature to the left the divergence is greatest opposite the third thoracic vertebra.

Relations of the Œsophagus.—The relations (Fig. 885) differ so widely in the neck and thorax that they must be described separately for each of those regions.

In the Neck.—Anteriorly lies the trachea—to the posterior membranous wall of which the œsophagus is loosely connected by areolar tissue—and in the groove at each side, between the trachea and œsophagus, the recurrent nerve ascends to the larynx (Fig. 885, A). Posteriorly lie the vertebral column and the longus colli muscles, from which the œsophagus is separated by the prevertebral layer of the cervical fascia. On each side are placed the carotid sheath with its contained vessels, and the corresponding lobe of the thyreoid gland and the inferior thyreoid artery. Owing to the deviation of the tube to the left in the inferior part of the neck, its relation to the carotid sheath and thyreoid gland is much more intimate on the left than on the right side.

In the Thorax.—The œsophagus passes successively through the superior and posterior mediastina, in the former lying close to the vertebral column, but in the latter advancing somewhat into the thoracic cavity and coming into contact with the back of the pericardium. The trachea still lies anterior to it as far as the fifth thoracic vertebra, where the trachea bifurcates. Immediately below that the œsophagus is crossed by the left bronchus (Fig. 885, C), and in the rest of its thoracic course it lies in the closest relation to the back of the pericardium. Posteriorly, in the upper part of the thorax, it rests on the longus colli muscles and the vertebral column; but below the bifurcation of the trachea, as already explained, it advances into the cavity of the posterior mediastinum, and is soon separated from the vertebral column by the vena azygos, the thoracic duct, the upper five aortic intercostal arteries of the right side, and in its lower part by the thoracic aorta as well.

On its *left side*, in the upper part of the thorax, lie the left pleura and the left subclavian artery, with the thoracic duct in a plane posterior to the artery; in the middle region, the aorta, and lower down the left pleura again, for a little way, before the œsophagus pierces the diaphragm. On the *right side* the tube comes into relation with the arch of the vena azygos, whilst the right pleura clothes it both below and above that level.

The two vagus nerves, after forming the anterior and posterior pulmonary plexuses, descend to the œsophagus, where they form, by uniting with one another and with the branches of the sympathetic, the anterior and posterior **œsophageal plexuses**. Lower down the left nerve winds round to the anterior, whilst the right turns to the posterior surface of the œsophagus, and in this relation they pass with the tube through the diaphragm to reach the stomach.

The **diaphragmatic portion**, about half an inch in length (1 to 1·5 cm.), corresponds to the œsophageal orifice (or canal) of the diaphragm. The plane of this orifice is very oblique or almost vertical, and its abdominal opening looks forwards and to the left, and but little downwards. Above and in front, it is bounded either by the posterior edge of the central tendon or by a few decussating fibres of the muscular portion of the diaphragm. At the sides and behind, on the other hand, the decussating bands from the two crura, which embrace the orifice, are so arranged that they turn a flat surface (not an edge) towards the opening, and thus, behind and at the sides, the orifice or canal is of some length; and on these aspects the tube is in contact with the diaphragm for a distance of 1 to $1\frac{1}{2}$ cm.

But this contact takes place not around a horizontal line, but in a very oblique plane corresponding to that of the orifice.

The œsophagus is connected to the boundaries of the orifice by a considerable amount of strong connective tissue, but it is extremely difficult, or impossible, to demonstrate any direct naked-eye connexion between the œsophageal muscular fibres and those of the diaphragm.

The **pars abdominalis** of the œsophagus is very short, for immediately after piercing the diaphragm the tube expands into the stomach. It lies against the œsophageal groove of the liver in front.

When the stomach is fully distended the abdominal part of the œsophagus almost disappears, being absorbed into the stomach in its distension.

The portion of the œsophagus which adjoins the stomach is sometimes described as consisting of two parts, namely, the **ampulla phrenica** and the **antrum cardiacum**. The former is a fusiform expansion of the tube, of variable length and girth, which lies within the thorax immediately above the point where the gullet is grasped between the two muscular margins of the œsophageal opening and the diaphragm. It lies in the lowest part of the posterior mediastinum where this is bounded anteriorly by the back of the diaphragm.

The antrum cardiacum is another name for the abdominal portion of the œsophagus. It is funnel-shaped, and expands towards the stomach.

Relation of the Aorta to the Œsophagus.—The arch of the aorta, passing back to reach the vertebral column, crosses to the left side of the œsophagus; consequently the descending thoracic aorta lies at first to its left; lower down, however, as the aorta passes on to the anterior aspect of the vertebral column, and the gullet inclines forwards and to the left, the aorta comes to lie posteriorly, and then, as the diaphragm is approached, it lies not only posteriorly, but also somewhat to the right of the œsophagus (Figs. 884 and 885).

Relation of the Thoracic Duct to the Œsophagus.—The thoracic duct, lying to the right of the aorta below, is not directly related to the œsophagus (Fig. 885, E); but higher up (Fig. 885, D and E) it lies posterior to it. About the level of the aortic arch the duct passes to the left, and above this (Fig. 885, B and A) will be found on the left side of the œsophagus, and on a plane somewhat posterior to it.

Relation of the Pleural Sacs to the Œsophagus.—Above the level of the arches of the aorta and of the vena azygos, between which the œsophagus descends, the pleuræ, though not lying in immediate contact with the œsophagus, are separated from it only by a little connective tissue, and on the left side also, behind the subclavian artery, by the thoracic duct (Fig. 885, B). Here, in thin bodies, the left pleura is very close to the œsophagus, and the thoracic duct, lying on its left side, may occasionally be seen through the pleural membrane. Below the arch of the azygos vein the right pleura clothes the right side of the œsophagus—and very often even a considerable portion of its posterior surface too, thus forming a deep recess behind it—almost as low down as the opening in the diaphragm. On the left side, below the level of the aortic arch, the left pleura comes in contact with the gullet, only for a short distance, just above the diaphragm (Fig. 885, E).

Variations.—The chief anomalies found in the œsophagus are: (1) Annular or tubular constrictions; (2) diverticula, of which the most interesting—known as "pressure pouches"—are usually situated on the posterior wall close to its junction with the pharynx, and these sometimes require surgical interference; (3) doubling in part of its course; and (4) communications between the trachea and œsophagus.

Structure of the Œsophagus (Fig. 888).—The œsophageal wall is composed of three proper coats—(1) *tunica muscularis*, (2) *tela submucosa*, and (3) *tunica mucosa*. In addition, it is surrounded by an outer covering of areolar tissue (4) *tunica adventitia*, by which it is loosely connected to the various structures related to it in its course. This loose covering permits of its free movement and of its increase in size, or of its diminution, during the act of swallowing.

The **tunica muscularis** is composed of two layers — an outer of longitudinal, and an inner of circular fibres. The *longitudinal layer* is highly developed, and, unlike the condition usually found in the digestive tube, it is as stout as, or in places stouter than, the circular layer. Its fibres form along the greater length of the tube an even covering outside the circular layer, and below they are continued into the longitudinal fibres of the stomach. Above, near the superior end of the œsophagus, the longitudinal fibres of each side, separating at the back, pass round towards the anterior aspect and form two longitudinal bands (Fig. 886), which run up on the front of the tube, and are attached by a tendinous band to the superior part of the posterior surface of the cricoid cartilage (Fig. 887).

The *circular muscular fibres*, though not forming such a thick layer as the longitudinal

fibres, are nevertheless well developed. Below, they are continued into both the circular

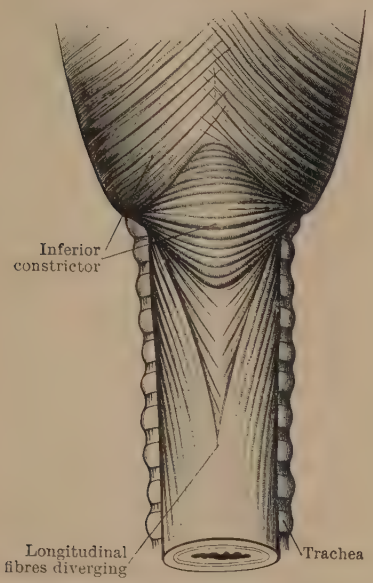

FIG. 886. — DISSECTION to show the arrangement of the muscular fibres on the posterior aspect of the œsophagus and pharynx. Traced upwards, the longitudinal muscular fibres of the œsophagus are seen to separate posteriorly; passing round to the sides, they form two longitudinal bands which meet anteriorly and are united to the cricoid cartilage, as shown in the next figure.

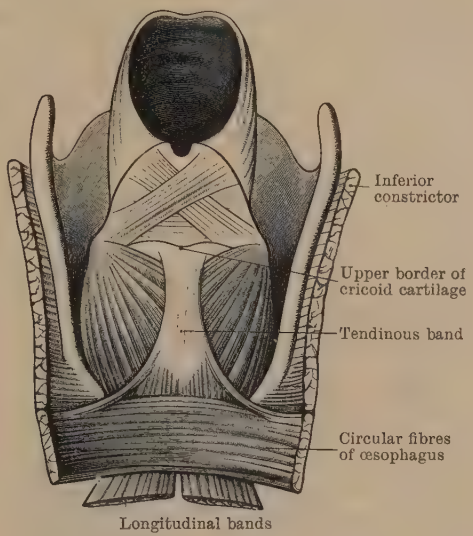

FIG. 887.—THE INFERIOR PART OF THE PHARYNX AND THE SUPERIOR PART OF THE ŒSOPHAGUS have been slit up from behind, and the mucous membrane removed to show the muscular fibres. The two longitudinal bands are seen passing round to the front to be attached by a common tendon to the superior border of the cricoid cartilage. See explanation of last figure.

and oblique fibres of the stomach. Above, they pass into the inferior fibres of the inferior constrictor of the pharynx.

At the superior end of the œsophagus the muscular fibres are entirely of the striated variety. Soon unstriped fibres begin to appear in increasing numbers, and in the inferior half or two-thirds only unstriped muscle is found.

The longitudinal fibres for about the superior fifth of the tube are entirely striped; in the second fifth striped and unstriped are mixed; whilst in the inferior three-fifths unstriped fibres alone are present. The circular fibres are entirely striated for the first inch; after this unstriped fibres appear; and in the inferior two-thirds, only unstriped muscle fibres are found.

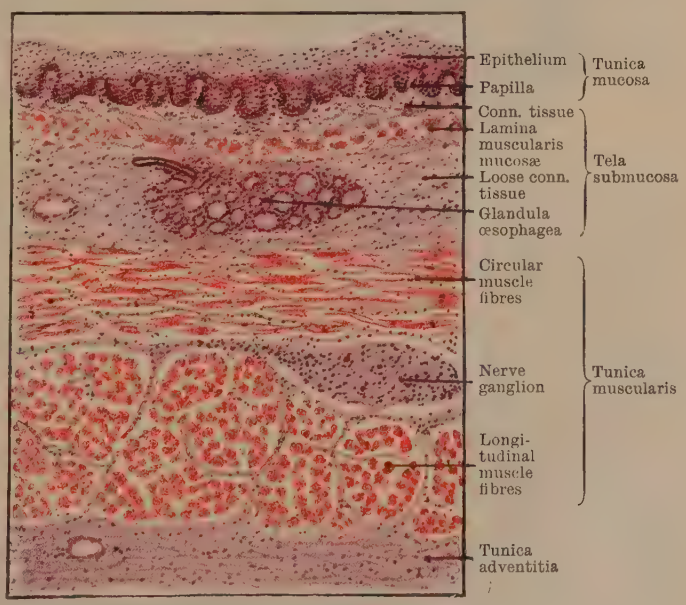

FIG. 888.—TRANSVERSE SECTION OF WALL OF HUMAN ŒSOPHAGUS.

The longitudinal fibres are often joined by slips of unstriped muscle, or elastic fibres, which spring from various sources, including the left pleura (*m. pleuro-œsophageus*, constant,

Cunningham), the bronchi (*m. broncho-œsophageus*), back of trachea, pericardium, aorta, etc. These slips assist in fixing the œsophagus to the surrounding structures in its passage through the thorax, and have been aptly compared to the tendrils of a climbing plant (Treitz).

The **tela submucosa**, composed of areolar tissue, is of very considerable thickness, in order to allow of the expansion of the tube during swallowing. It connects the mucous membrane loosely to the muscular coat, and admits of the former being thrown into folds when empty. In this coat are contained the numerous racemose mucous glands (glandulæ œsophageæ) which open into the cavity of the œsophagus (Fig. 888).

The **tunica mucosa** is of a grayish-pink colour, much paler than that of the pharynx, and of a firm and resistant texture. It is covered with a thick stratified, squamous epithelium, on the surface of which the openings of numerous glands are found. Inferiorly, its junction with the gastric mucous membrane is indicated by a distinct, irregularly dentated or crenated line, which runs transversely round the tube. In carefully preserved specimens the smooth mucous membrane of the œsophagus above this line contrasts strongly with the mamillated gastric mucous membrane below.

Owing to the inelasticity of this coat, and the fact that it is but loosely connected to the muscular coat by the submucosa, it is thrown into a series of longitudinal folds when the œsophagus is empty and contracted; hence the stellate lumen often seen in sections of the gullet.

Glands.—Numerous racemose mucous glands, the **glandulæ œsophageæ**, large enough to be seen distinctly with the naked eye, are found in the submucosa. They are pretty evenly distributed over the whole tube, and do not appear to be more numerous towards either end. In addition to these, other glands, resembling closely those of the cardiac end of the stomach, are found in the mucous membrane of certain portions of the œsophagus. They are entirely confined to the mucosa, and do not extend beyond the lamina muscularis mucosæ. These glands are specially numerous at both the upper and lower ends of the tube.

Vessels and Nerves.—Its **arteries** consist of numerous small branches derived, in the neck, from the inferior thyreoid, in the thorax, from the bronchial arteries and thoracic aorta, and in the abdomen, from the left gastric artery, and also from the left inferior phrenic.

The **veins** form a plexus on the exterior of the œsophagus, from which branches pass, in the lower part of the tube, to the coronary vein of the stomach, and, higher up, to the azygos, and thyreoid veins. There is thus established on the lower part of the œsophagus a free communication between the portal and systemic veins.

The **lymph vessels** pass to the inferior set of deep cervical glands in the neck, and to the posterior mediastinal glands, many of which, of large size, are seen around the tube, in the thorax.

The **nerves** are derived from the recurrent, and from the cervical sympathetic in the neck, from the vagus and sympathetic nerves in the thorax.

THE ABDOMINAL CAVITY.

As the remaining parts of the digestive system lie within the abdomino-pelvic cavity it will be necessary to describe that cavity, and to refer briefly to its lining membrane—the peritoneum—before passing on to the consideration of the viscera which are contained within it.

The abdomino-pelvic cavity is that portion of the cavity of the trunk which lies below the diaphragm. Its wall is composed in part of bones, muscles, tendons, fascia, etc., and in the cavity lie the greater part of the digestive, urinary, and generative systems of organs, as well as blood-vessels, nerves, and other structures. The internal surface of the greater part of the wall of the cavity, and of the external surfaces of the viscera, are clothed by a continuous smooth membrane, the peritoneum. The contained organs lie in contact with one another or with the wall, and the so-called cavity is merely a potential space between the peritoneal surfaces of adjacent viscera. When air is admitted, the viscera fall away from one another and a space is formed, in place of the capillary interval which exists under normal conditions between them.

In the following description the term **abdomen** or **abdominal cavity** is used to indicate the region enclosed by the muscular and bony walls, and the term **peritoneal cavity** the potential space inside the peritoneal membrane between the viscera.

Shape.—In vertical section the cavity is of a somewhat oval form, with the

long axis directed vertically. The superior end is wider than the inferior. In transverse section it is almost reniform, flattened from before backwards, and is encroached upon in the median plane posteriorly by the projection forwards of the vertebral column to such a degree that the front of the vertebral column lies at no great distance from the back of the anterior abdominal wall (usually $2\frac{1}{2}$ to 3 inches), while on each side of the vertebral column there is a deep recess, occupied by the kidneys and portions of the intestine.

The abdominal cavity is divisible into the **abdominal cavity proper** and the **pelvis minor**. Vertical section of the trunk shows that the **pelvis minor** (O.T. **true pelvis**) lies below and behind the abdominal cavity, of which it forms a funnel-shaped termination. The long axis of the funnel is directed downwards and backwards.

The **superior aperture of the pelvis minor** (Figs. 217 and 218, p. 256), which separates the two natural divisions of the cavity, is formed behind by the base of the sacrum, at the sides by the linea terminalis of each hip bone, and in front by the pubic crests and the symphysis pubis. In the erect position it usually makes an angle of about 55 to 60 degrees with the horizontal. The two portions of the abdominal cavity which the superior aperture separates meet at an angle, the abdomen proper extending almost vertically upwards from it, whilst the pelvic cavity slopes backwards and slightly downwards.

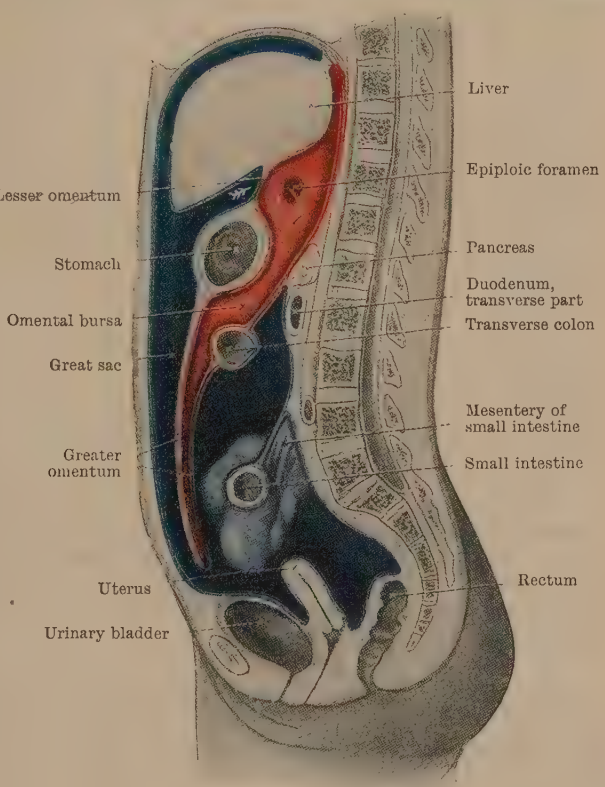

FIG. 889.—DIAGRAMMATIC MEDIAN SECTION OF FEMALE BODY, to show the abdomino-pelvic cavity and the peritoneum on vertical tracing. The great sac of the peritoneum is blue and is represented as being much larger than in nature; the bursa omentalis is coloured red; the peritoneum in section is shown as a white line: and a white arrow is passed through the epiploic foramen from the great sac into the bursa omentalis.

As the walls of these two regions are markedly different, the boundaries will be considered separately.

Boundaries of the Abdomen Proper.—The cavity is limited *above* by the concave vault of the diaphragm, which is dome-shaped and presents a right and a left cupola separated by an intervening depression. On the superior surface of each cupola is placed the base of the corresponding lung, whilst between them, on the depression, rests the inferior surface of the heart.

During expiration, the diaphragm ascends almost to the level of the right nipple, and may reach the superior border of the fifth rib, or even the middle of the fourth intercostal space. On the left side it is one-half to one inch (12-25 mm.) lower, and in the median plane it crosses the inferior extremity of the body of the sternum about the level of the seventh rib cartilage.

Below, the cavity is continued into the cavity of the pelvis minor.

The *anterior wall* is formed by the aponeuroses of the three flat abdominal muscles, obliquus externus, obliquus internus, and transversus abdominis, together with the two recti, which latter constitute powerful braces for the wall, on each side of the median plane.

Anteriorly, below the junction of abdomen and pelvis, lies the pubic symphysis. The body of the pubis looks upwards as well as posteriorly, and appears to form a support or floor for the viscera contained within the anterior part of the abdominal cavity.

The *side walls* are formed by the muscular portions of the obliqui and transversi muscles, and below by the iliac bones and the iliacus muscles.

Finally, the cavity is limited *posteriorly* by the lumbar portion of the vertebral column, with the crus of the diaphragm and psoas major muscle on each side, and the quadratus lumborum still more laterally. The iliac bones also enter into the formation of the inferior portion of the posterior wall.

The superior portion of the cavity lies under cover of the ribs, which afford considerable protection to that part of the abdomen, particularly at the sides and posteriorly. Anteriorly, on the other hand, the ribs are wanting below the sternum, and there the abdominal wall is formed only of aponeuroses and muscles. But even at the sides and back there is a considerable zone, usually one to two inches wide, between the lower ribs above and the crest of the ilium below, which has no bony support except that afforded by the vertebral column.

Whilst the circumference of the diaphragm is attached to the inferior part of the thoracic framework anteriorly and laterally, and to the lumbar vertebræ posteriorly, the central portion of the dome, on the other hand, namely, the central tendon, is placed high up, under cover of the ribs, and in a more or less horizontal plane. As a result, the peripheral muscular part slopes upwards and medially from the circumference of the thoracic framework to the central tendon, and lies for a considerable distance in contact with the deep surface of the ribs; thus the diaphragm comes to form, not only the roof of the cavity, but it also enters into the formation of the sides, the posterior wall, and, to a less extent, of the anterior wall; and *almost as much of the cavity of the abdomen as of the thorax lies under shelter of the ribs.*

Owing to the fact that the boundaries of the abdomen are formed chiefly of muscles, it follows that its walls are capable of contraction to a very considerable extent, and the size of the cavity can consequently be altered in all directions. Its chief changes in form are due to the descent or elevation of the diaphragm, the contraction or relaxation of the anterior wall and the side walls, and the raising or lowering of the pelvic floor.

The **pelvic cavity** is bounded in front and at the sides by the portions of the hip bones below the level of the linea terminalis. Those portions of the bony wall are partly clothed by the obturator internus muscles, and, internal to those muscles, by the parietal portion of the pelvic fascia, as low down as the arcus tendineus. The posterior wall is formed by the pelvic surface of the sacrum, covered on each side by the piriformis muscle. That wall (as represented by the piriformes muscles) meets the side wall at the anterior border of the greater sciatic foramen; through that foramen the piriformis passes out, thus closing up what would otherwise be a large aperture in the parietes of the cavity. The floor is composed of the two pairs of muscles which form the pelvic diaphragm, namely, the levatores ani and the coccygei—covered by the visceral layer of the endopelvic fascia. Those muscles pass, on each side, from the side wall of the pelvis, downwards and medially towards the median plane, and present a concave superior surface towards the pelvic cavity.

The internal surface of the muscles forming the walls is lined by an envelope of **fascia**, which separates the muscles from the extraperitoneal connective tissue and peritoneum. This fascial layer is distinguished in different localities as: (1) the *fascia transversalis*, on the anterior and side walls, lining the deep surface of the transversalis muscle and continuous above with the fascia clothing the inferior surface of the diaphragm; (2) the *fascia diaphragmatica*; (3) the *fascia iliaca*, on the posterior wall, covering the psoas and iliacus muscles; and (4) the *fascia endopelvica*, lining the pelvis.

Apertures.—Certain apertures are found in the muscular walls of the abdomen. They are: the three openings in the diaphragm for the passage of the inferior vena cava, the œsophagus, and the aorta, respectively; the apertures in the pelvic floor, through which the rectum, the urethra, and the vagina in the female, reach the

surface; the inguinal canal, through which the spermatic funiculus (or the round ligament) passes; and lastly, the femoral canal, a small passage which extends downwards from the abdomen along the medial side of the femoral vessels. The latter two, particularly, constitute on each side weak points in the abdominal wall, through which an inguinal or a femoral hernia may occur. Similar protrusions may also occur at other points in the abdominal and also in the pelvic wall.

Tela Subserosa (O.T. **Extraperitoneal** or **Subperitoneal Connective Tissue**).—Between the fascia which covers the deep surfaces of the abdominal muscles and the peritoneum is found a considerable quantity of connective tissue, more or less loaded with fat, known as the tela subserosa. It is part of an extensive fascial system which lines the whole of the body cavity, outside the various serous sacs, and it is continued on the several vessels, nerves, and other structures which pass from the trunk into the limbs and neck.

In the abdomen it is divisible into a parietal and a visceral portion. The former lines the walls, whilst the latter passes between the layers of the peritoneal folds to the viscera. The two portions of the extraperitoneal tissue are continuous with one another, and contain in their whole extent a vascular plexus, through which a communication is established between the vessels of the abdominal wall on the one hand, and those of the contained viscera on the other. The parietal tela subserosa is also freely supplied by a network of nerve fibres, derived from cerebro-spinal nerves.

The *parietal portion* is thin and comparatively free from fat over the roof and anterior wall of the abdomen, where the peritoneum is firmly attached. In the pelvis minor, on the other hand, the tissue is loose and fatty, and it is continued up for some inches on the anterior abdominal wall above the pubes, and permits of the ascent of the bladder during its distension, in the interval between the peritoneum and the anterior abdominal wall. There also the urachus and the obliterated umbilical arteries will be found passing up in its substance. On the posterior wall the tissue is large in amount and fatty, particularly where it surrounds the great vessels and the kidneys.

From the parietal portion the *visceral expansions* are derived, in the form of prolongations around the various branches of the aorta. Those expansions are connected with the areolar coats of the blood-vessels and pass with them into the mesenteries and other folds of the peritoneum, and thus reach the viscera.

The chief uses of the tela subserosa are: (1) to unite the peritoneum to the fascial and muscular layers of the abdominal wall; (2) to connect the viscera to those walls and to one another in such a loose manner that their distension or relaxation may not be interfered with. That would not be the case if the connecting medium were firm or rigid; (3) in addition, it is a storehouse of fat, forms sheaths for the vessels and nerves, and establishes, through its vascular plexus, communication between the parietal vessels and those distributed to the abdominal viscera.

Subdivision of the Abdomen Proper.—Owing to the large size of the cavity, and in order to localise more correctly the position of the various organs contained within it, the abdomen proper is artificially subdivided by two horizontal and two sagittal planes (Fig. 890).

Of the two *horizontal planes*, one divides the trunk at the level of the lower border of the tenth costal cartilage; this is known as the **subcostal plane**, and the line where it intersects the abdominal wall is the **subcostal line**. The second horizontal plane is at the level of the highest point of each iliac crest which is visible from the front; this point corresponds to the tubercle seen on the external lip of the crest, about two inches posterior to the anterior superior spine, and can be easily located; the line and plane are consequently known as the **intertubercular line** and **plane**, respectively.

The *sagittal planes* are drawn, one on each side, perpendicularly upwards from a point on the **inguinal ligament** of Poupart midway between the anterior superior spine and the symphysis pubis. The planes and the corresponding lines are known as the **lateral planes** and **lines** respectively.

By the two horizontal planes the abdomen is divided into *three zones*, a superior or **costal**, a middle or **umbilical**, and an inferior or **hypogastric zone**. By the two

perpendicular planes each zone is subdivided into three regions, a central and two lateral. Thus, in the upper zone, we get a **hypochondriac region** or **hypochondrium** on each side, and an **epigastric region** or **epigastrium** in the centre. Similarly, the umbilical zone is divided into **right** and **left lumbar regions**, with an **umbilical region** between. And the hypogastric zone has a **hypogastric region** or **hypogastrium** in the centre, with **right** and **left iliac regions** at the sides.

In addition, the portion of the abdominal wall above the body of the pubis is known as the *suprapubic region*, and that immediately above the inguinal ligaments as the *inguinal region*.

The three central divisions, namely, the epigastric, umbilical, and hypogastric

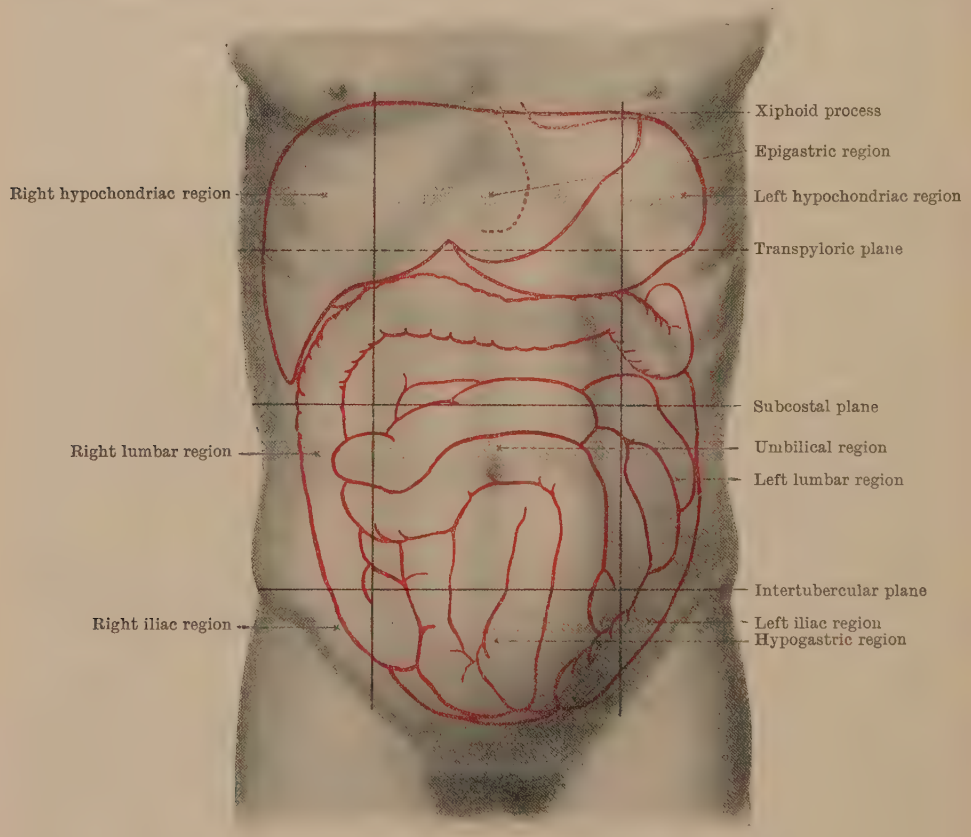

FIG. 890.—PLANES OF SUBDIVISION OF THE ABDOMINAL CAVITY, AND OUTLINE TRACING OF THE LIVER, STOMACH, AND INTESTINE IN RELATION TO THE ANTERIOR ABDOMINAL WALL.

The oblique position of the stomach and the high position of the transverse colon are largely due to the fact that the subject was in the horizontal position.

regions, can conveniently be further subdivided by the median sagittal plane, passing through the middle of the body, into right and left halves.

The superior horizontal, or subcostal, plane passes posteriorly, through the superior part of the third lumbar vertebra, or the fibro-cartilage between the second and third lumbar vertebræ. The intertubercular plane cuts through the middle or superior part of the fifth lumbar vertebra.

The inferior margin of the tenth costal cartilage frequently corresponds to the most dependent part of the thoracic framework. Often, however, the eleventh costal cartilage descends $\frac{1}{4}$ to $\frac{1}{2}$ inch lower. Nevertheless, the tenth cartilage is selected in drawing the subcostal plane, for two chief reasons, namely, it is visible from the front as a rule, and it is comparatively fixed, whilst the eleventh, being a floating rib, is much more movable, is variable in length, and more difficult to locate.

Another plane which is of some practical value is the *transpyloric plane* (Addison). This is a horizontal plane which is taken to intersect the trunk at the level of the first lumbar vertebra. That level is ascertained during life by taking

the mid-point of a line drawn, on the surface of the trunk, from the superior border of the sternum to the upper border of the symphysis pubis. The same level is obtained usually, but not so accurately, by taking the mid-point of a line drawn from the xiphi-sternal articulation to the umbilicus.

PERITONEUM.

The **peritoneum** is the serous membrane which lines the abdominal cavity and invests most of the abdominal viscera, to a greater or less degree. Like the pleuræ, pericardium, and other serous sacs, it is composed of a thin layer of fibrous tissue, containing numerous elastic fibres, covered over on the side turned towards the cavity of the sac by a layer of flattened endothelial cells forming the *tunica serosa*. Like them, too, the peritoneum in the male is a completely closed bag, but in the female this is not the case, for the ostium abdominale of each uterine tube opens into the sac, whilst the ostium uterinum of that tube communicates with the interior of the uterus, and thus, indirectly, with the exterior of the body. Normally the membrane secretes only sufficient moisture to lubricate its surface, otherwise the sac is perfectly empty, and its opposing walls lie in contact, thus practically obliterating its cavity.

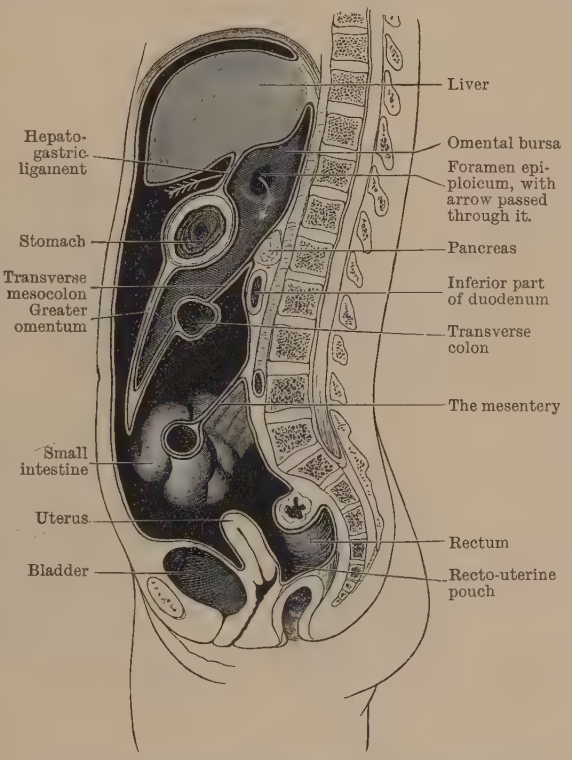

Fig. 891.—Diagrammatic Median Section of Female Body, to show the peritoneum on vertical tracing. The great sac of the peritoneum is black and is represented as being much larger than in nature; the bursa omentalis is very darkly shaded; the peritoneum on section is shown as a white line; and a white arrow is passed through the foramen epiploicum from the great sac into the bursa omentalis.

The serous lining permits of the movements of the contained viscera during any changes in size or form which they or their containing cavity may undergo, and the stomach and intestines are free to move with the least degree of friction when any change takes place either in the organs themselves or in their surroundings.

The peritoneum is united so intimately to many of the viscera that it appears at first sight to be a superficial layer of the organs themselves rather than a separate membrane.

The peritoneum covering an organ is termed *visceral peritoneum*; where it lines the walls or forms mesenteries and omenta it is termed *parietal peritoneum*.

The term peritoneal cavity has already been explained (p. 1148).

In the adult its arrangement is complicated by the changes which occur during their development in the form and position of many of the viscera, and it is necessary to explain briefly some of the changes which modify the original simple arrangement of the peritoneum.

The peritoneum represents the smooth lining membrane of a large portion of the body cavity, or cœlom.

Many of the abdominal viscera originally lie dorsal to this membrane on the posterior body wall, with their ventral surfaces only in contact with the lining membrane of the cœlom.

The greater part of the intestinal tube, on the other hand, projects forwards from the body wall into the body cavity, and is connected with the dorsal wall by a narrow strand of connective tissue and by blood-vessels. The lining membrane of the abdominal wall covers each surface of this lamina, and the ventral and lateral surfaces of the intestinal tube.

Organs showing the first relationship are said to lie "behind" the peritoneum, or to be "partly invested" by it.

In the condition of the intestine described, the organ is said to be "completely invested" and to have a "mesentery" connecting it to the abdominal wall.

The intestine originally has a continuous dorsal mesentery, and its proximal portion is connected to the ventral wall above the level of the umbilicus by a ventral mesentery.

As the organs develop and alter in their position and form, the peritoneum

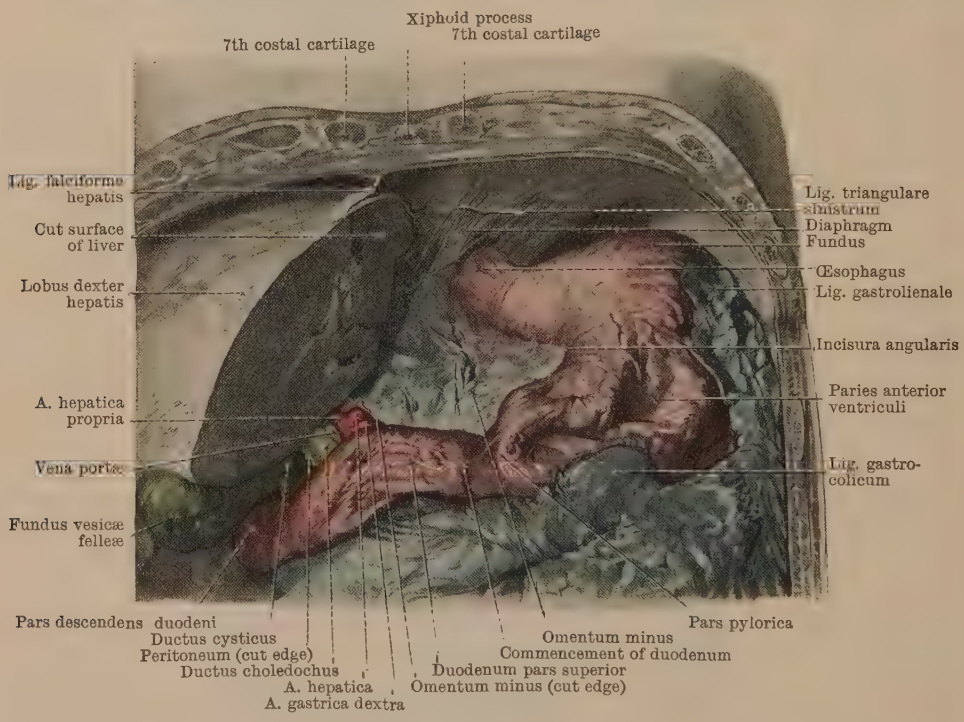

FIG. 892.—THE LESSER OMENTUM.

The left lobe of the liver has been removed, and also the anterior layer of the hepato-duodenal ligament. The view is taken looking upwards as well as backwards.

covering them is involved, and the mesenteries grow or become stretched. Layers of peritoneum may come to lie in contact with one another, and blend, leaving no trace of their original double origin.

With the formation of successive organs, especially of the liver and of the spleen, a mesentery which originally was simple may come to contain more organs than one, and so portions of it pass from one organ to another, and not from the wall to an organ. Such folds are usually termed "omenta."

Mesenteries are folds of peritoneum which unite portions of the intestine to the posterior abdominal wall, and convey to them their vessels and nerves. There are several mesenteries, *e.g.* the *mesenterium* (*mesentery proper*), which connects the jejunum and ileum to the posterior abdominal wall, the *mesocolon transversum* (*transverse mesocolon*), the *mesocolon pelvicum* (*pelvic mesocolon*), and occasionally others (see pp. 1206, 1209, 1211).

Of other folds the principal ones are:—

(1) **Omentum Majus.**—The *greater omentum* hangs down like an apron from the transverse colon, in front of the coils of the jejunum and ileum. It consists

embryologically of four layers of peritoneum, two anterior and two posterior. The four layers form a thin, translucent, and often perforated membrane. The anterior two layers were originally connected with the stomach above, and passed down in front of the transverse colon, but as development proceeds they become adherent to the anterior surface of the transverse colon. The fold which extends from the stomach to the colon is termed the gastro-colic ligament. The anterior and the posterior folds are often partly or wholly blended, but if the anterior two layers are separated from the posterior two and from the front of the transverse colon, the anterior layers of the greater omentum are directly continuous with the layers of the gastro-colic ligament. This condition is that usually described in English text-books as the normal adult condition and is represented in Fig. 891, where the gastro-colic ligament is separated from the transverse colon, and passes in front of the transverse colon directly into the anterior layers of the omentum majus, and the great omentum thus descends from the stomach above.

(2) **Omentum Minus.**—The *lesser omentum* is a fold passing from the inferior surface of the liver to adjacent organs. It consists of two, or occasionally three, portions:—

(*a*) The *ligamentum hepatogastricum*, a thin, translucent, and sometimes fenestrated peritoneal fold, extending from the lesser curvature of the stomach to the left end of the porta hepatis, the fossa of the ductus venosus, and partly also to the concave surface of the left lobe of the liver and the caudate process. At the lesser curvature of the stomach it is continued into the peritoneal coats of the anterior and posterior surfaces of that organ. It contains the vessels (blood and lymph) of the lesser curvature, some lymph glands, and a twig from the left vagus nerve which goes to the liver.

(*b*) The *ligamentum hepatoduodenale* passes from the porta hepatis to the pars superior of the duodenum. On the left this fold is continuous with the hepato-gastric ligament, on the right it ends in a rounded margin. Traced downwards, the layers of peritoneum which form it clothe the commencement of the duodenum on two sides, and are continued into the transverse mesocolon. In it lie the hepatic artery, portal vein, bile duct, with lymphatic vessels and nerves.

(*c*) The *ligamentum hepatocolicum* is an occasional fold passing from the region of the gall-bladder to the transverse colon and right colic flexure.

(3) **Ligamentum Gastrolienale.**—The *gastro-splenic ligament* (O.T. *gastro-splenic omentum*) is a double layer of peritoneum extending between the greater curvature of the stomach (at the fundus and adjacent portion of the body) and the hilum of the spleen, and continuous below with the gastro-colic ligament. It contains gastric branches of the splenic vessels.

(4) The **ligamentum gastrocolicum** extends from the greater curvature of the stomach to the transverse colon. It consists of two layers of peritoneum, continuous above with the layers on the anterior and posterior surfaces of the stomach, and below with the anterior layers of the great omentum. In it lie the right and left gastro-epiploic vessels, nerves, and some lymph glands.

In English text-books this is not usually recognised as a separate ligament, but is considered to be a portion of the greater omentum, and to pass downwards in front of the transverse colon. It will be found, however, that the arrangement in the adult is usually that described above.

Other folds, specially named, but described elsewhere, are the ligaments of the liver, the so-called "false ligaments" of the bladder, the lieno-renal ligament, and the broad ligaments of the uterus.

Whilst the greater part of the general peritoneal cavity lies anterior to the various abdominal viscera, it should be mentioned that there is a recess of considerable size derived from it, situated mainly behind the stomach; this is known as the *bursa omentalis* (O.T. *small sac*), and it will be described in detail later. The aperture through which one sac communicates with the other is termed the *foramen epiploicum* (*Winslowi*) (O.T. *foramen of Winslow*).

Peritoneal "Adhesions" and Variations.—In addition to the folds mentioned above, many other peritoneal bands and folds are to be made out.

(1) The gall-bladder is often united to the pars superior of the duodenum by a

dense, strong layer of connective tissue, which blends with the hepato-duodenal ligament.

(2) The duodeno-jejunal junction is occasionally firmly joined by similar bands to the transverse meso-colon.

(3) About the cæcum, processus vermiformis, terminal part of the ileum, and proximal part of the ascending colon, it is almost usual to find bands of fairly dense tissue passing (*a*) from the colon to the lateral abdominal wall, (*b*) from the terminal portion of the ileum to the cæcum, (*c*) from the cæcum itself to the parietes.

Such bands are usually ascribed to "peritonitis."

(4) The great omentum may be united to the anterior surface of the ascending colon.

(5) Fibrous bands often pass especially from the left side of the iliac colon to the parietes.

They have been ascribed to faults in development, to peritonitis, and to mechanical traction, and it is not yet possible to state definitely the exact mode and cause of their origin.

Contents of the Abdomen.—The following structures are found within the abdomino-pelvic cavity:—

1. The greater part of the *alimentary canal*, viz., stomach, small intestine, and large intestine.
2. *Digestive glands:* the liver and pancreas.
3. *Ductless glands:* the spleen and the two supra-renal glands.
4. *Urinary apparatus:* the kidneys, ureters, bladder, and part of urethra.
5. The internal *generative organs*, according to the sex.
6. *Blood-vessels* and *lymph vessels*, and *lymph glands.*
7. The abdominal portion of the cerebro-spinal and sympathetic *nervous systems.*
8. Certain *fœtal remains.*
9. The *peritoneum*—the serous membrane which lines the cavity, and is reflected over most of its contained viscera.

VENTRICULUS.

The **stomach** is a dilatation of the digestive tube immediately after it enters the abdomen (Figs. 884 and 893). It constitutes a receptacle in which the food accumulates after its passage through the œsophagus, and in it take place some of the earlier processes of digestion, resulting in the conversion of the food into a viscid fluid, known as chyme. The chyme escapes through the pylorus into the small intestine, where the digestive processes are continued.

The form and the position of the stomach present great variations, not only among different individuals, but also in the same individual at different times. The degree to which it is filled, the size and position of adjacent organs, the condition of the abdominal walls, and even the assumption of the erect or the recumbent attitude can influence its shape and relations.

Of recent years, examination of the stomach by X-rays has afforded information, otherwise unattainable, of the shape and position of the stomach in life, and of the changes which it undergoes. The results obtained by this method have considerably modified conceptions regarding the stomach in the living. A necessary preliminary to the proper comprehension of these appearances is a careful study of the stomach as it presents itself to anatomical examination.

General Shape.—In shape, the stomach is irregularly piriform, with a wide end lying deeply in the hollow of the diaphragm, mainly in the left hypochondriac region, and a narrow tapering extremity which passes downwards and forwards, and is bent over to the right side, in the epigastric region.

The long axis of the organ forms a spiral curve, directed downwards, anteriorly and to the right, and finally backwards.

Size and Capacity of the Stomach.—Probably no organ in the body varies more in size within the limits of health than the stomach. Moreover, as its tissues change so rapidly after death, measurements made on softened and relaxed organs are not only worthless but quite misleading.

The *length* of the stomach in the fully distended condition is about 10 to 11 inches

(25 to 27·5 cm.), and its greatest *diameter* not more than 4 to 4½ inches (10 to 11·2 cm.); whilst its *capacity* in the average state rarely exceeds 40 ounces, or 1 quart.

The distance in a direct line from the cardiac to the pyloric orifice varies from 3 to 5 inches (7·5 to 12·5 cm.), and that from the cardia to the summit of the fundus from 2½ to 4 inches (6·2 to 10·0 cm.).

As regards the *weight*, the average of twelve wet specimens freed from their omenta was found to be 4¾ oz. (135 grms.), with a maximum of 7 oz. (198·45 grms.) and a minimum of 3½ oz. (99·22 grms.). Glendinning gives the weight as 4½ oz.

In the child at birth the stomach is scarcely as large as a small hen's egg, and its capacity is about 1 oz. (28·3 grms.). In shape it corresponds pretty closely to that of the adult, and the fundus is well developed. It is vertical in position.

The stomach presents the following parts for examination:—

Two surfaces, an anterior (**paries anterior**) directed forwards and to

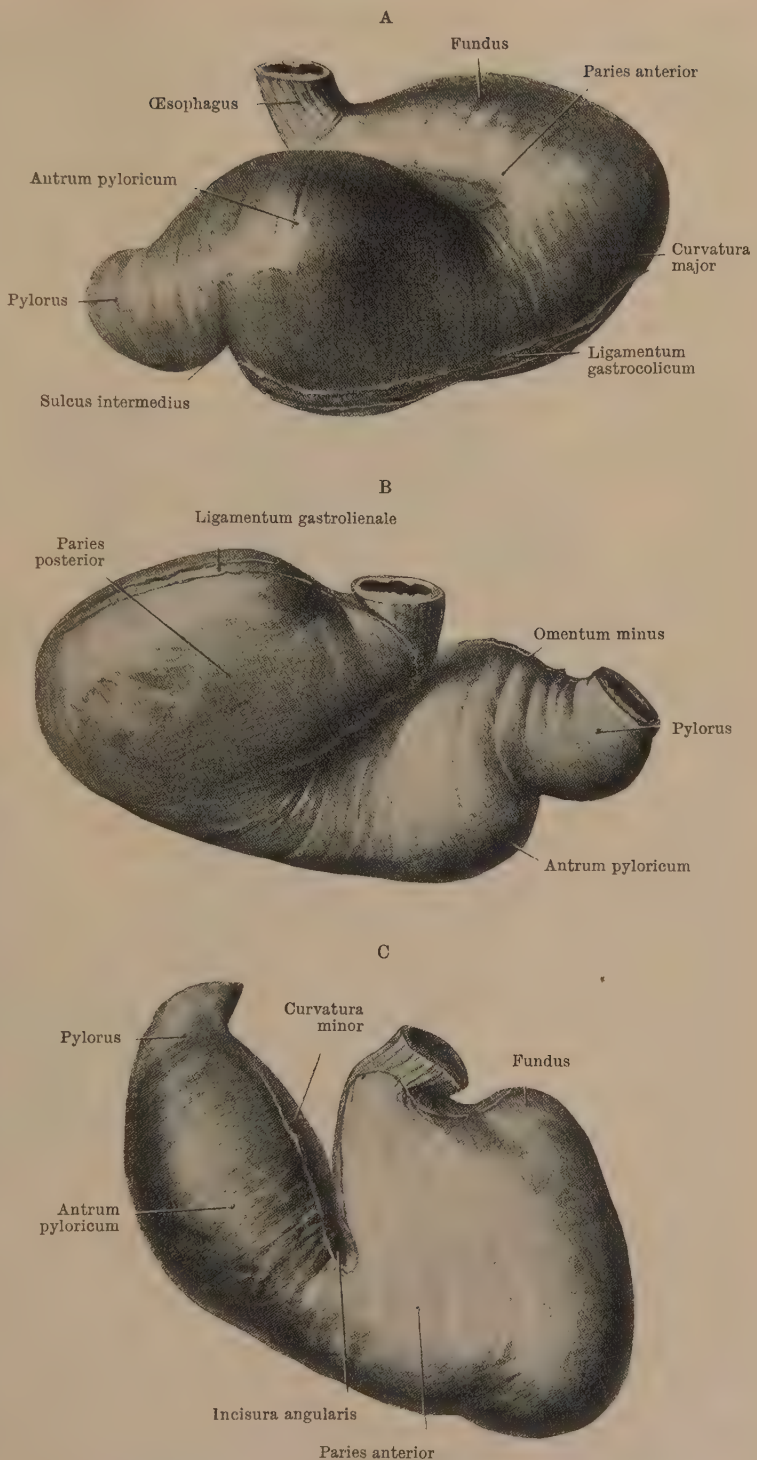

FIG. 893.—THREE VIEWS OF A STOMACH FIXED BY FORMALIN INJECTION *IN SITU*.

A. From the front. B. From the back. C. From above.

The orientation of the stomach was determined by the insertion of long pins into it in the sagittal, frontal, and transverse planes. These views show the comparatively horizontal position of the stomach associated with the horizontal posture of the trunk. They also show the partial division into chambers produced by temporary constrictions ot the stomach wall fixed by the action of formalin.

the left, and a posterior (**paries posterior**) which looks posteriorly and also to the right. These surfaces meet above and to the right at the lesser curvature, **curvatura minor**, and below at the greater curvature, **curvatura major**. At the superior end of the lesser curvature the œsophagus enters the stomach, at the œsophageal opening, or cardia, while at the inferior end the stomach passes into the duodenum at the pylorus. The dome-shaped portion to the left of the œsophagus is the **fundus**, while the remainder of the stomach is divisible into the body, **corpus ventriculi**, and the pyloric portion, **pars pylorica**.

Cardia.—The œsophageal opening is situated at the superior end of the lesser curvature, on the right side of the fundus, and more on the anterior than the posterior surface of the stomach.

Around this opening the muscular walls of the œsophagus and the mucous membrane become continuous with corresponding coats of the stomach wall. The longitudinal muscular coat passes onwards into a longitudinal set of fibres, and the circular œsophageal fibres pass into the circular muscular coat. The whitish-coloured stratified squamous epithelium of the œsophagus is continuous with the pinkish-coloured columnar epithelial wall of the stomach, and the junction is marked by a sharp irregular line running round the margin of the opening.

The orifice itself is oval or angular rather than round, being compressed from side to side.

To the right of the orifice, the right margin of the œsophagus merges with a slight curve into the lesser curvature of the stomach, while on the left side there is a deep notch, the **incisura cardiaca**, between the inferior end of the œsophagus and the fundus, in which lies a strong projecting ridge of the right crus of the diaphragm.

This notch on the outer surface produces a fold in the interior of the stomach, which may assist in closing the œsophageal opening, and this, with the decussating fibres of the diaphragm, and the strengthened circular fibres of the inferior end of the œsophagus, forms a kind of sphincter for this orifice which serves to prevent regurgitation from the stomach under ordinary conditions.

The cardia is very deeply placed, and lies about four inches behind the sternal end of the seventh left costal cartilage, at a point one inch from its junction with the sternum. Posteriorly it corresponds to the level of the eleventh thoracic vertebra.

Owing to the fixation of the œsophagus by its passage through the diaphragm, and the close connexion between the stomach and the diaphragm near the cardia where the peritoneum is absent, this is the most fixed part of the whole organ.

Pylorus.—The **pyloric orifice** is placed at the extremity of the pyloric end of the stomach, and its position is indicated upon the surface of the stomach by a slight annular constriction which is most marked at the curvatures, termed the pyloric ring.

Its position is also indicated by an arrangement of blood-vessels at the pyloric ring, which is nearly constant. On the peritoneal surface a thick vein passes upwards from the lower side somewhat more than half-way on the anterior surface, and from the upper border a second vein reaches downwards in the same line, nearly, if not quite, meeting the first (W. J. Mayo).

The **pyloric constriction** marks the junction of stomach and duodenum, and there the various coats of these portions meet with one another.

The peritoneal covering of the stomach is continued onwards on to the first part of the duodenum, and the longitudinal fibres of the stomach (stratum longitudinale) are in part continued onwards into the longitudinal fibres of the duodenal coat, but many of them bend inwards into the thickened ring around the opening, and spread out in diverging bundles, which interlace with the most superficial of the circular fibres, and some of them reach and terminate in the subjacent submucosa.

The circular muscular fibres of the stomach (stratum circulare) are not continuous directly with those of the duodenum. On the contrary, at the orifice they become very much increased in number, and they form a thick ring, or

sphincter, which is separated from the circular muscular coat of the duodenum by a fibrous septum.

This sphincteric ring is sharply marked off from the duodenum, but there is no sharp line of demarcation on the gastric side, for there the ring gradually merges into the circular muscular coat of the cylindrical pyloric canal, whose wall when contracted is nearly as thick as the sphincteric ring.

The gastric mucous membrane (**tunica mucosa**) is continued into the mucous membrane of the duodenum at the distal margin of the sphincter. The junction cannot be recognised by superficial inspection. The gastric mucosa is considerably thickened where it covers the sphincter muscle. When examined post mortem in

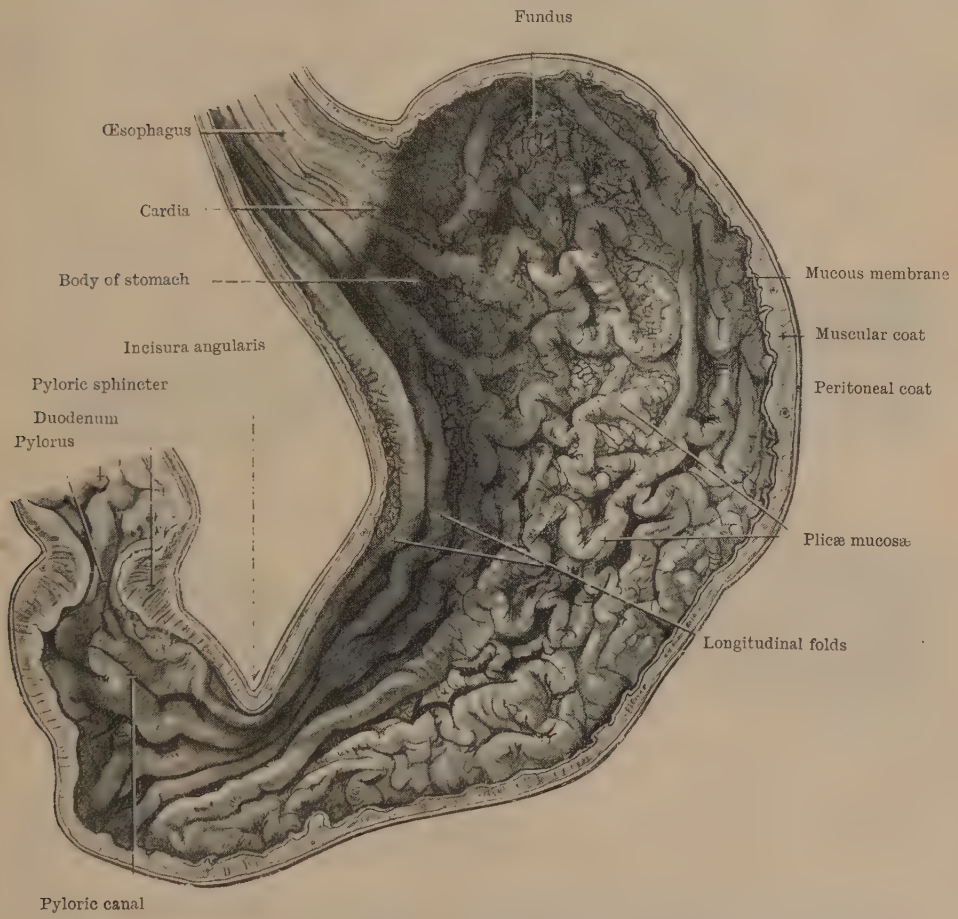

FIG. 894.—INTERIOR OF STOMACH, SHOWING THE MUCOSA AND THE PARTS OF THE STOMACH IN A CONDITION OF MODERATE FILLING.

the ordinary way, the aperture, viewed from the duodenal side, is somewhat oval in form. When seen from the opposite side, it presents a stellate appearance, owing to the fact that the rugæ of the gastric mucous membrane are continued up to the orifice.

The orifice is directed horizontally backwards, and to the right. When the stomach is full, however, it looks almost directly backwards, or even slightly to the left side.

The pylorus rests on the neck of the pancreas below and posteriorly, and is overlapped by the liver above and anteriorly. When the stomach is empty the pylorus is usually placed near (*i.e.* within ½ inch, 12 mm., of) the median plane, below the left lobe or sometimes the quadrate lobe of the liver, and at the level of the first lumbar vertebra, or the fibro-cartilage between this and the second lumbar. During disten-

sion it is pushed over beneath the quadrate lobe for a variable distance, but very rarely more than 1½ or 2 inches to the right of the median plane. Its average position can be marked on the surface of the body by the intersection of two lines; one drawn horizontally half-way between the top of the sternum and the pubic crest (Addison), the other drawn vertically a little way (½ inch, 12 mm.) to the right of the median plane.

During the earlier stages of gastric digestion the sphincter pylori is strongly contracted and the aperture firmly closed, but it opens intermittently to allow of the passage of properly digested portions of the food. As digestion advances the sphincter probably relaxes somewhat; but in hardened bodies a really patent pylorus is rarely or never found, which would seem to indicate that the pylorus is normally closed, or nearly so, and that its opening is an active rather than a passive condition, as in the case of the anal canal.

As regards its size, the pylorus is stated to be about ½ inch (12·5 mm.) in diameter, but there is no doubt that this represents neither its full size nor its calibre when at rest. Foreign bodies with a diameter of ¾ to 1 inch have been known to pass through the pylorus without giving rise to trouble, even in children. On the other hand, when at rest, with an empty stomach and duodenum, the aperture is practically closed.

Curvatura Ventriculi Minor.—The **lesser curvature** is directed towards the

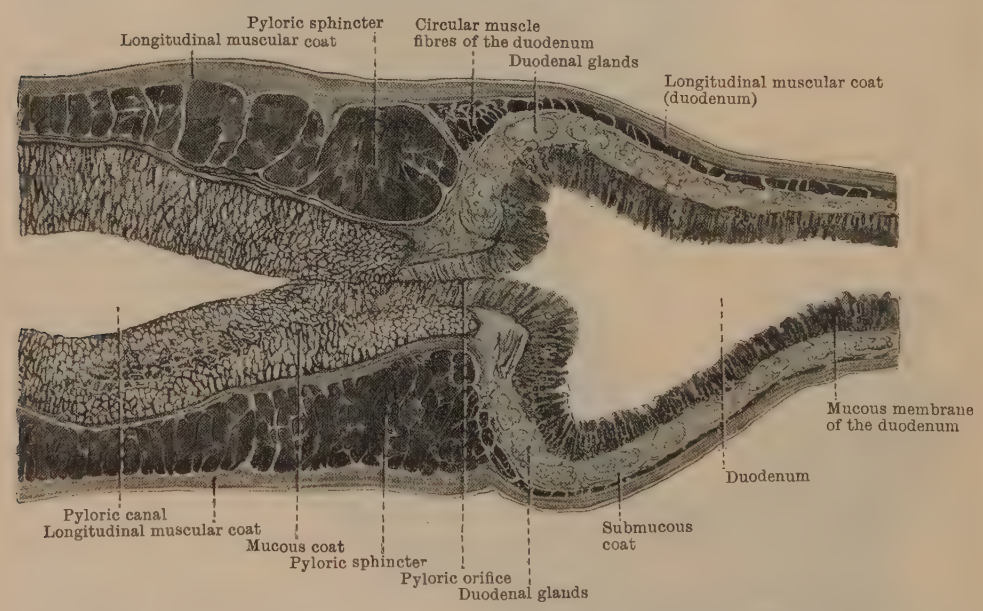

Fig. 895.—Longitudinal Section through the Pyloric Canal and Commencement of the Duodenum in a New-born Child. (From Stiles.)

liver. To it is attached the fold of peritoneum called the hepato-gastric ligament which connects the stomach and liver.

While the lesser curvature is, on the whole, concave, it consists of two portions which meet and form a sharp angle, called the *incisura angularis*. The superior or left portion is the longer of the two, is nearly vertical, and continues the direction of the right margin of the œsophagus, while the inferior or right portion is more nearly horizontal, when viewed from the front. The position, depth, and acuteness of the angle between these two segments varies with the degree of distension of the stomach. When the pyloric portion of the stomach is full, the inferior portion of the lesser curvature becomes distended, and that portion of the border becomes convex in outline. In length the lesser curvature measures some 3 to 4 inches.

Curvatura Ventriculi Major.—The **greater curvature of the stomach** is usually over three times as long as the lesser curvature, and corresponds to a line drawn from the cardia over the summit of the fundus (Fig. 893), and then along the most projecting portion of the stomach as far as the pylorus. In general, it is directed to the left

and forwards, but at its beginning, near the cardia, it of course looks in a different direction. The great curvature corresponds in the greater part of its length to the attachment of the gastro-splenic and gastro-colic ligaments, folds of peritoneum passing to the spleen and to the transverse colon respectively; and in close relation to it, between their layers, run the right and left gastro-epiploic vessels.

This border of the stomach, like the lesser curvature, does not present a uniformly curved outline. Towards the pylorus a notch is often found, called the **sulcus intermedius**. The portion to the right of this sulcus is known as the **pyloric canal**.

On the left side of this notch, the greater curvature bulges forwards, forming a chamber called the **antrum pyloricum**, and the projecting rounded prominence which it forms is, in some phases of digestion, marked off from the rest of the body of the stomach by a temporary indentation. Other indentations which are sometimes found on the greater curvature, or the body of the stomach, are probably due to temporary peristaltic waves of contraction.

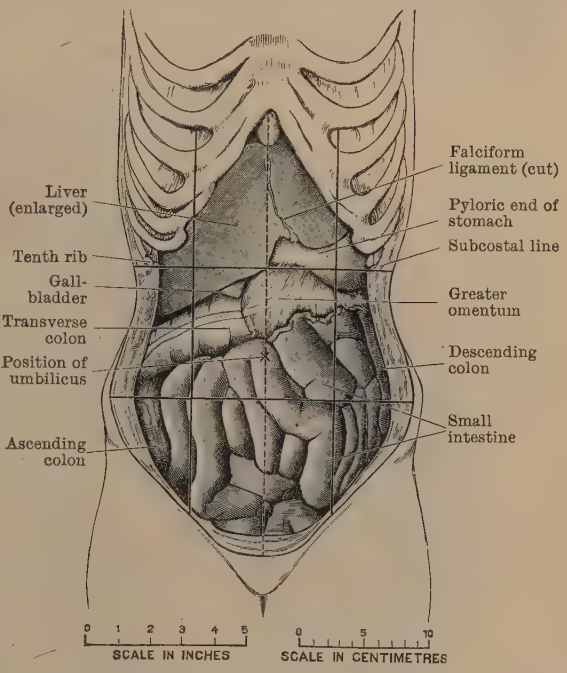

FIG. 896.—ABDOMEN OF FEMALE, SHOWING DISPLACEMENTS RESULTING FROM TIGHT LACING.

The liver is much enlarged, and extends on the left side to the ribs, where it was folded back on itself for over an inch. The pyloric end of the stomach and the beginning of the duodenum are quite superficial below the liver, and all the viscera are displaced downwards. (From a photograph of a body hardened by injections of formalin.)

Paries Anterior.—The **anterior wall of the stomach** is more convex and more extensive than the posterior. When the stomach is distended, it is in contact with the inferior surface of the left lobe of the liver medially, the vault of the diaphragm laterally, and the anterior abdominal wall below (Fig. 893). When the stomach is empty, on the other hand, the transverse colon doubles up in front of it, and separates its anterior surface from the liver and diaphragm and abdominal wall.

Paries Posterior.—The **posterior wall** looks downwards and posteriorly. It is more flattened than the anterior, and is moulded by the structures upon which it rests.

Thus, to the left is a flattened area, passing on to the fundus, which is in contact with the diaphragm and the spleen. To the right of the fundus the superior portion of the posterior wall, nearly vertical, is in contact with the left kidney and supra-renal gland and the diaphragm; and the inferior portion, more horizontal, is in contact with the pancreas, transverse mesocolon, and transverse colon. These structures constitute the posterior wall of the bursa omentalis of the peritoneal cavity.

Between these two areas, the wall comes into contact with the splenic artery as it runs along the superior border of the pancreas.

The different portions into which the stomach may be divided are as follows:—

Fundus Ventriculi.—The **fundus** is that portion of the stomach which lies above a horizontal plane drawn through the œsophageal opening. It is rounded or dome-shaped. This shape seldom alters, whatever the condition of the stomach may be. It is usually filled with gas.

Corpus Ventriculi.—The **body of the stomach** extends from the fundus to the incisura angularis on the lesser curvature, and to the notch on the greater

curvature already described. It forms a rounded chamber, capable of great distension, but when the stomach is empty it contracts to a narrow tube-like structure. As the stomach is seldom completely empty, the body usually tapers from the fundus to the proximal end of the pyloric portion (Fig. 894).

Pars Pylorica.—The **pyloric portion** of the stomach extends from the incisura

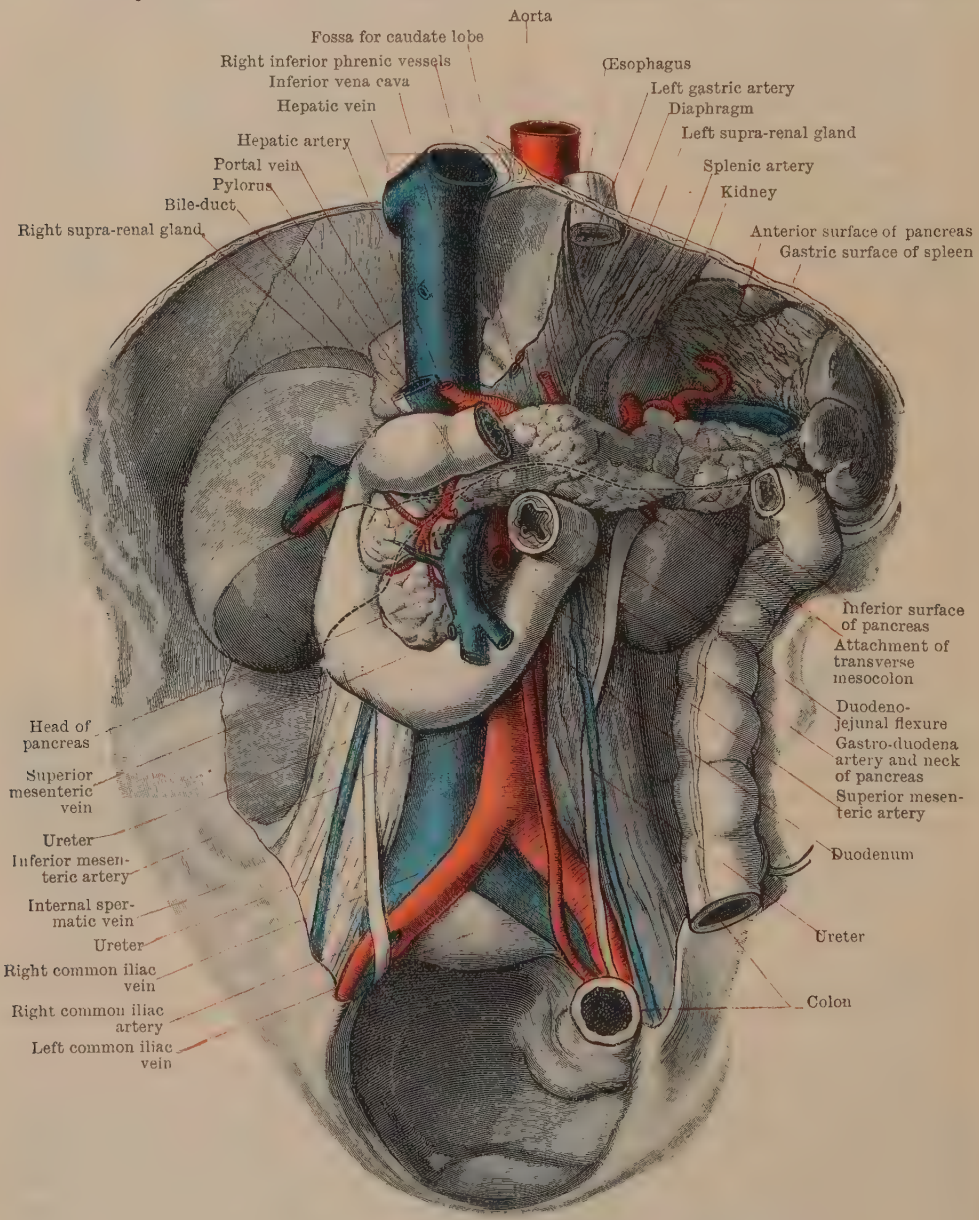

FIG. 897.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney, and also the fossa for the caudate lobe. When the liver was taken out, the vena cava was left behind. The stomach bed is well shown. (From a body hardened by chromic acid injections.)

angularis in the lesser curvature, and a variable and inconstant notch on the greater curvature, as far as to the pyloric orifice (Figs. 893, 902).

It differs from the body of the stomach in being more tubular in shape, and possessing thicker walls.

It has been divided anatomically into two portions, the **pyloric canal** and the **antrum pyloricum** respectively.

The **pyloric canal** is a short more or less tubular portion rather more than an inch in length, extending from the sulcus intermedius on the greater curvature to the pyloric constriction. The proximal portion, called the **pyloric antrum**, is more expanded. It is not clearly demarcated from the body of the stomach

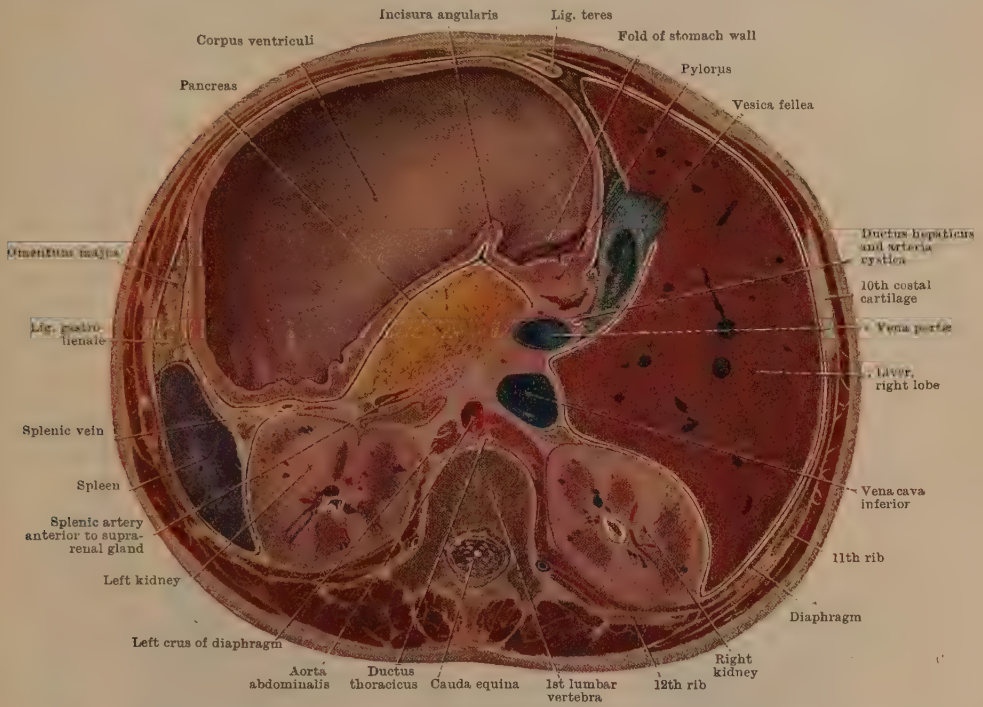

FIG. 898.—TRANSVERSE SECTION OF THE TRUNK AT THE LEVEL OF THE FIRST LUMBAR VERTEBRA. Showing relations of stomach, pancreas, kidneys, etc. From a subject ten years old.

by any constant line of division on the greater curvature. On the lesser curvature it extends from the incisura angularis to the pyloric canal, and it is occasionally pouched outwards on the side of the greater curvature so as to form a chamber or pouch, the "camera princeps" of His.

RELATIONS AND CONNEXIONS OF THE STOMACH.

When the stomach has been removed, after the body has been hardened, a chamber or recess is exposed, known as the **stomach chamber**. It is (Figs. 897 and 899) a space in the upper and left portion of the abdominal cavity with an arched roof, an irregularly sloping floor, and an anterior wall. The *roof* is formed partly by the visceral surface of the left lobe of the liver, and in the rest of its extent by the left cupola of the diaphragm, which arches gradually downwards behind and on the left to meet the floor.

The *floor* or "*stomach bed*" (Fig. 897) is a sloping shelf on which the posterior surface of the stomach rests, and by which it is supported. The bed is formed posteriorly by the superior pole of the left kidney (with the supra-renal gland) and the gastric surface of the spleen; anterior to this, by the wide anterior surface of the pancreas; and more anteriorly still, by the transverse mesocolon running forwards above the small intestine, from the anterior edge of the pancreas to the transverse colon (Fig. 899), which completes the floor anteriorly.

Finally, the *anterior wall* of the stomach chamber is formed by the abdominal wall, between the ribs on the left and the liver on the right side.

Peritoneal Relations.—The stomach is almost completely covered by peritoneum—the anterior surface being clothed by that of the general peritoneal sac, and the posterior surface by the anterior layer of the bursa omentalis (see p. 1155). From the lesser curvature the hepato-gastric ligament extends to the liver, whilst to the greater curvature the gastro-lienal and gastro-colic ligaments are attached. Finally, a small peritoneal fold, known as the *gastro-phrenic ligament*, is found running from the stomach up to the diaphragm along the left side of the œsophagus.

A small irregularly triangular area (Fig. 893), about 2 inches wide and 1½ inches from above downwards, during moderate distension of the stomach, on the posterior surface below and to the left of the cardia, is not covered with peritoneum, and over it the organ is in direct contact with the diaphragm, occasionally also with the superior extremity of the left kidney and the suprarenal gland. From the left angle of this "uncovered area" the attachment of the gastro-lienal ligament starts; and at the right angle is the commencement of a fold through which the *left gastric* artery passes to the stomach. This fold is called the *left gastro-pancreatic* fold.

The *right gastro-pancreatic* fold is a fold of peritoneum passing from the right extremity of the superior part of the pancreas to the first part of the duodenum. It encloses the hepatic artery.

Displaced Stomach (Fig. 896).—As a result of disease, or of constriction of the superior part of the abdomen, the stomach is occasionally displaced in position and distorted in shape, so that instead of running obliquely forwards, downwards, and to the right, it is placed nearly vertically along the left side of the vertebral column, in which direction

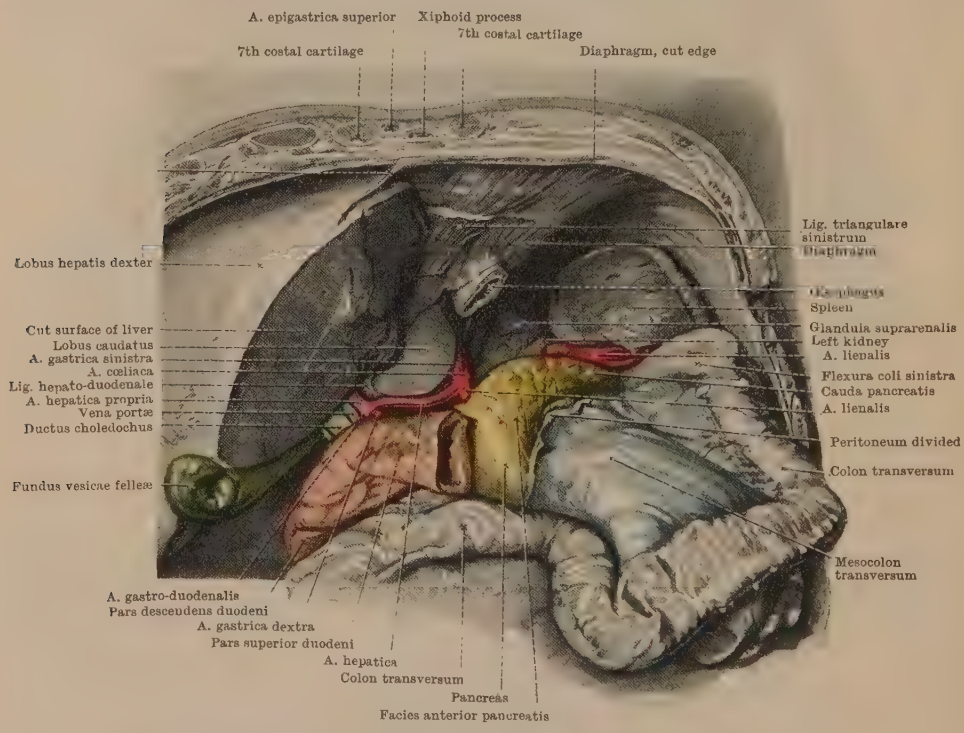

FIG. 899.—STOMACH CHAMBER VIEWED FROM THE FRONT AND FROM BELOW.
From the specimen figured in Fig. 892, after removal of the stomach.

it has a very considerable length. Its inferior part bends rather suddenly, and runs upwards and to the right to join the pylorus, which is often placed quite superficially below the liver. As a result of the displacement, the left extremity of the pancreas is pushed downwards from the horizontal until it assumes almost a vertical position. The narrowing and inversion of the inferior margin of the thoracic framework at the same time constricts the stomach about its middle, and may lead to a bilocular condition.

Hour-glass or Bilocular Stomach.—This is a condition of the organ, by no means rare, in which the stomach is more or less completely separated into two divisions—a cardiac and a pyloric—the normal arrangement in certain rodents and other animals. As a rule the former division is the larger, but occasionally the two are nearly equal, or the pyloric portion may exceed the cardiac in size. Sometimes the condition is temporary, and the result of a vigorous contraction of the circular muscular fibres at the seat of constriction. In other cases it is permanent, and may be due to cicatricial contraction after gastric ulcer, or to some other pathological condition. The condition is more frequent in the female than the male, and is rarely found in the fœtus or child.

Position of the Stomach.—*When empty*, or nearly so, the stomach lies in the left hypochondrium and left part of the epigastrium, with its fundus directed posteriorly towards the diaphragm, its long axis lying almost in a horizontal

plane and its pyloric part running to the right to join the duodenum. In this state the whole organ is narrow and attenuated, particularly the pyloric part, which is contracted, and resembles a piece of thick-walled small intestine.

When distended, both the cardiac and pyloric parts become full and rounded (Fig. 893). It still lies within the hypochondriac and epigastric regions; but in exceptional cases, or in extreme distension, it may pass down below the subcostal plane and reach into the umbilical and left lumbar regions. As a result of the general increase in length which takes place during distension, the pylorus is moved a variable distance to the right beneath the quadrate lobe of the liver, and at the same time the long axis of the whole organ becomes much more oblique, running forwards, downwards, and to the right. Finally there is

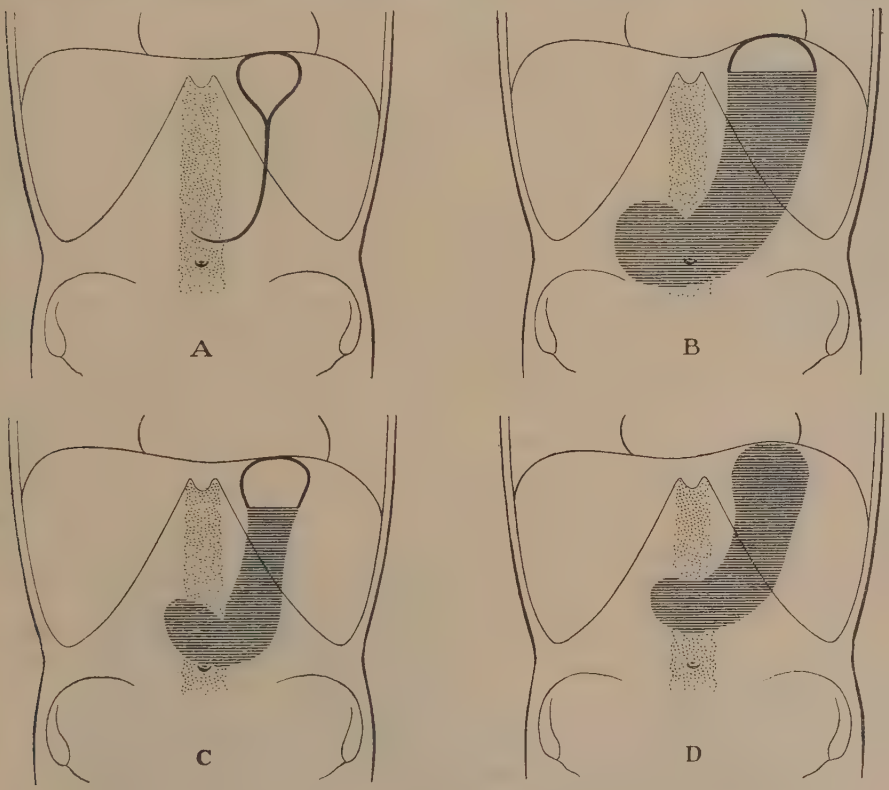

FIG. 900.

A. Empty stomach in vertical position as defined by the X-rays.
B. Filled stomach in vertical position as seen with the X-rays.
C. Half-filled stomach in vertical position as seen with the X-rays.
D. Half-filled stomach in horizontal position as seen with the X-rays.

developed a special dilatation of the pyloric part, known as the *antrum pyloricum*, which in extreme distension is carried so far to the right that it may even reach to the hypochondrium.

Shape and Position of the Stomach as seen by X-Ray Examination.—Examination of the stomach by means of X-rays after a "bismuth meal" has given important information about the shape and position of the stomach in the living, and about the changes which occur as the stomach fills and empties.

These examinations corroborate, in great part, the conclusions which have been arrived at by the study of formalin specimens so far as the shape of the stomach, and its division into parts, are concerned. In regard, however, to the position and direction of the stomach, X-rays show that the stomach in the living, and especially in the erect attitude, is more vertical than it is after death, and when the body is examined in the horizontal position. In the upright position, in fact, the long

axis of the organ appears to be nearly vertical. The general shape and position of the stomach in the vertical position, moderately distended, is shown in Fig. 900. From this it will be seen that not only is the body of the stomach nearly vertical, but that the greater curvature reaches down to the umbilicus, and may descend beyond it even below the level of a line joining the iliac crests. The pyloric part is directed upwards, as well as backwards, and the pylorus is not usually the lowest point of the stomach.

The other anatomical features of the stomach described above are well brought out. Thus the fundus is a hemispherical dome, lying to the left of the terminal portion of the œsophagus, and continuous in outline with the body of the stomach. It usually contains gas, and appears translucent to X-rays. The body is of uniform outline, and the pyloric part is marked off from it by the incisura angularis, on the lesser curvature. Further, the pyloric part shows division into pyloric antrum and pyloric canal. The incisura angularis and sulcus intermedius are distinct.

The position of the stomach is greatly influenced by attitude and by the condition of the abdominal muscles. Contraction of the abdominal muscles can elevate the stomach from 5 to 13 cm., or 2 to 5 inches, and the change from the horizontal to the erect attitude alters the height of the inferior border from 2 to 10 cm. This sinking which occurs in the alteration from the horizontal to the erect attitude, accounts largely for the differences found between the stomach seen in the post-mortem room or on the operating table and the stomach displayed by means of X-rays. Thus, if the stomach figured on p. 1161 be considered fixed at the cardiac end, and somewhat fixed at the pylorus, and the pyloric antrum and greater curvature should sink downwards, the shape, as seen from the front, would closely resemble the X-ray appearances found often in the living.

The empty stomach is a contracted tubular organ, except at the fundus, where it appears to be always dilated. When food is taken it passes from the œsophageal orifice along the lesser curvature towards the pyloric end of the stomach. It has been shown (p. 1168) that the folds of mucous membrane found near the lesser curvature form channels along which the food is directed in this course. This portion of the stomach is sometimes known as the "gastric canal," and it has been shown that it is derived from the lower part of the œsophagus. The distal portion of the stomach dilates for some distance, or at least as far as the pyloric canal.

As the stomach becomes filled the whole of the body of the organ becomes dilated, but the fundus and cardiac portion more particularly so, and these two latter regions act as a storehouse.

There is no definite division of this portion from the remainder of the stomach by a permanent sphincter, but the peristaltic waves of contraction begin about the middle of the organ, and form a fleeting constriction between the two parts.

As peristalsis goes on, the tubular pyloric part relaxes somewhat. The waves of peristalsis here become so deep as to divide this portion into chambers. The food substances are forced through the pylorus by successive waves of peristalsis, and in the form, usually, of jets which impinge against the posterior aspect of the duodenal wall.

Should there be undigested masses, the pyloric valve relaxes to allow them also to pass into the duodenum.

Structure of the Stomach.

The stomach wall is composed of four coats—namely, from without inwards: (1) Tunica serosa, (2) tunica muscularis, (3) tela submucosa, and (4) tunica mucosa (Fig. 901).

Tunica Serosa.—The serous coat is formed of the peritoneum, the relations of which to the stomach have already been described. It is closely attached to the subjacent muscular coat, except near the curvatures, where the connexion is more lax.

Tunica Muscularis.—The muscular coat, which is composed of unstriped muscle, is thinnest in the fundus and body, much thicker in the pyloric portion, and very highly developed at the pylorus. It is made up of three incomplete layers—an external, *stratum longitudinale*; a middle, *stratum circulare*; and an internal of oblique muscular fibres, *fibræ obliquæ*.

The *stratum longitudinale* consists of longitudinal fibres, continuous with those of the œsophagus from which they radiate over the stomach wall (Fig. 903, A). They are most distinct on each side of the lesser curvature, where they form two strong bands, termed the tæniæ of the lesser curvature, and to a lesser degree at the greater curvature. Over the two surfaces they are present as an extremely thin and irregular sheet. Towards the pylorus the longitudinal fibres grow much thicker, and also much tougher and more closely united, and they take part in the formation of the **pyloric valve** (see p. 1158).

A specially condensed band of these can be often made out both on the front and back at the antrum pyloricum, the form of which is said to be due to their presence. These bands are known as the **ligamenta pylori** (pyloric ligaments).

The *stratum circulare* is continuous with the more superficial of the circular fibres at the lower end of the œsophagus (Fig. 903). It forms a set of U-shaped bundles which loop over the lesser curvature at the right of the cardia, and pass downwards and to the left on both surfaces. Further to the right these looped fibres are succeeded by circles which surround the organ completely. Traced towards the narrow end of the stomach, the circular bundles grow thicker, and at the pylorus they undergo a further increase, giving rise to the pyloric sphincter which surrounds the orifice as a thick muscular ring.

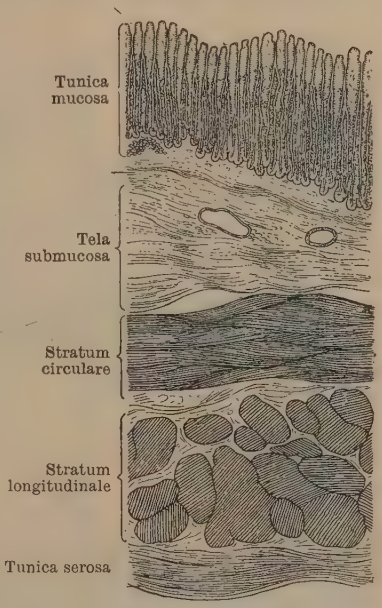

FIG. 901.—TRANSVERSE SECTION THROUGH THE WALL OF A HUMAN STOMACH. × 250.

Many authorities believe that the circular coat is arranged in a manner slightly different from that given above, namely, that its fibres form a ring around the fundus, similar to those described above as being formed by the oblique coat.

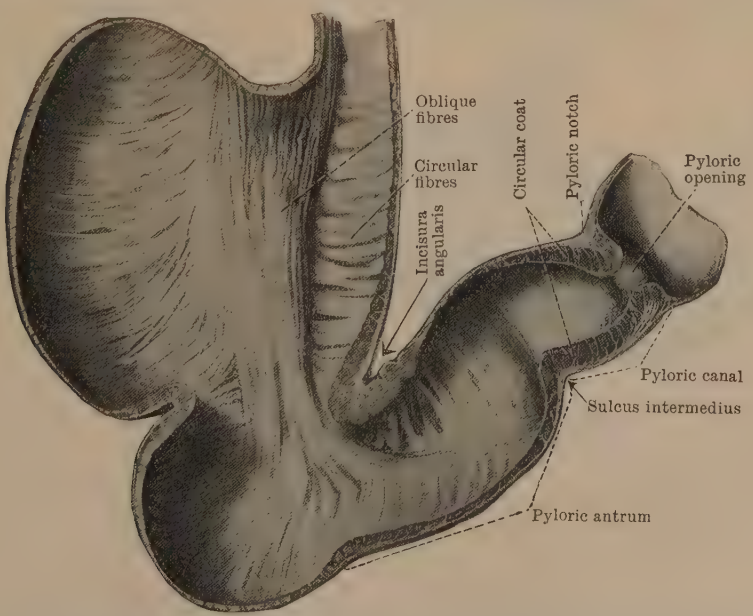

FIG. 902.—MUSCULAR COAT OF THE STOMACH, seen from within after removal of the mucous and submucous layers. The anterior half of the stomach is shown, viewed from behind (Cunningham).

The present description was made out by Professor Birmingham from a series of his own dissections, and is retained as being correct.

The *fibræ obliquæ*, forming the inner layer, consist of fibres which are arranged on the fundus and adjacent parts of the stomach, in much the same manner as those of the

middle layer are on the body and pyloric part of the organ (Fig. 903, C). They are continuous above with the deeper circular fibres of the inferior end of the œsophagus, and form U-shaped bundles which loop over the stomach immediately to the left of the cardia, and run very obliquely downwards and to the right for a considerable distance on both surfaces of the organ. These looped fibres, as they pass to the left, gradually become less oblique, and finally form circles which surround the wide end of the stomach completely, even as far as the summit of the fundus. The oblique fibres can be most readily shown by removing the circular fibres on either surface below the cardia. When traced towards the right, they will be found to terminate by turning down and joining the fibres of the circular layer.

FIG. 903.—THE THREE LAYERS OF THE MUSCULAR COAT OF THE STOMACH. A, External or longitudinal layer; B, Middle or circular layer; C, Internal or oblique layer. *a*, Longitudinal fibres of œsophagus; *b*, Superficial circular fibres of œsophagus passing into circular fibres of stomach in B; *c*, Deep circular fibres of œsophagus passing into oblique fibres of stomach in C; *d*, Oblique fibres forming rings at the fundus; *e*, Submucosa.

Tela Submucosa. — The submucous coat is a layer of strong but loose connective tissue, which lies between and unites the muscular and mucous coats (Fig. 901). It is more loosely attached to the muscular and more closely to the mucous coat, and it forms a bed in which the vessels and nerves break up before entering the mucous membrane.

Tunica Mucosa.—In the fresh state the mucous coat is of a reddish-gray colour and of moderate consistence. After death, the colour turns to a darker gray, and the whole membrane becomes softer and more pulpy. It is thicker (over 2 mm.) and firmer in the pyloric than in the cardiac part, and is thinnest at the fundus. When the stomach is empty all three outer coats, which are extensile, contract; whilst the mucous coat is thrown into numerous prominent folds or *rugæ*, which project into the interior. These are, in general, longitudinal in direction, with numerous cross branches. They disappear when the stomach is distended. Along the lesser curvature are three or four long, narrow, very constant ridges, which pass without a break from the œsophageal orifice towards the pyloric part of the stomach (Fig. 894). These ridges are parallel to one another, and are apparently never obliterated. Between them are deep furrows, which form channels leading from the œsophageal orifice to the pyloric portion. At the junction of the body and pyloric portions, at the level of the sulcus intermedius, is often a transverse fold of mucosa, which is of some size, termed the plica pre-pylorica.

When the surface of the mucous coat is examined in a *fresh* stomach, it is seen to be marked out into a number of small, slightly elevated, polygonal areas, *areæ gastricæ*, by numerous linear depressions; the mucous membrane is consequently said to be mamillated (Fig. 904, A). These little areas, which measure from 1 to 6 mm. in

diameter, are beset with numerous small pits, *foveolæ gastricæ*, about ·2 mm. wide, which are the mouths of the gastric glands, and they are so closely placed that the amount of surface separating them is reduced (particularly in the pyloric portion, where the gland mouths are widest) to a series of elevated ridges, *plicæ villosæ*, resembling villi on section. Although the gland mouths cannot be seen with the naked eye, a very slight magnification is sufficient to show them clearly; it is also possible to see the gland tubes leading off from the bottom of each (Fig. 904, B).

Minute Structure of the Mucous Coat.—In structure the mucous coat consists of an epithelial covering composed of long columnar cells, and of numerous tubular glands, *glandulæ gastricæ*, which are prolonged outwards from this surface, and which are enclosed in a delicate connective tissue stroma, with some small lymph nodules, *noduli lymphatici gastrici*. The bases of the glands reach outwards to the lamina muscularis mucosæ, a layer consisting of an external longitudinal and an internal circular layer of plain muscle fibres.

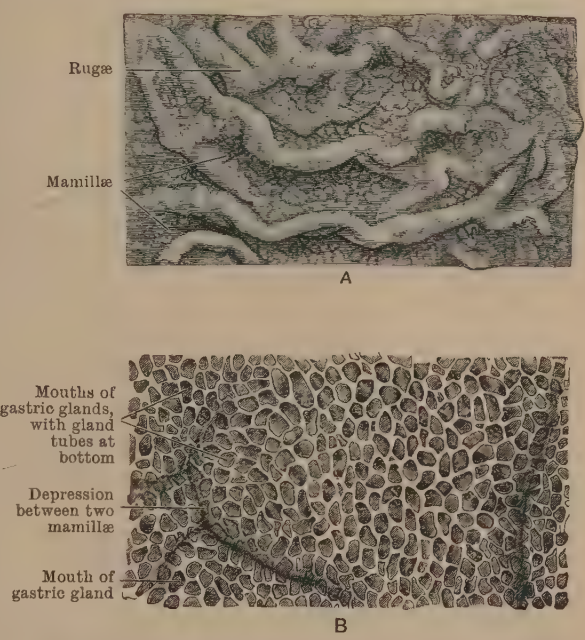

FIG. 904.—MUCOUS MEMBRANE OF THE STOMACH. A, Natural size; B, Magnified 25 diameters. In A the rugæ and the mamillated surface are shown. In B the gland mouths (foveolæ gastricæ), with the gland tubes leading off from some of them, and the ridges separating the mouths (plicæ villosæ) are seen.

Glandulæ Gastricæ.—These consist of a duct terminating in one or more secreting tubules. The duct is lined with columnar epithelial cells, similar to those which cover the surface of the mucous membrane. Three varieties of glands are found in different regions of the stomach, and are named from their position—

(1) **Cardiac Glands.**—These glands are situated close to the œsophageal opening. The duct terminates in a single long tubule, which is lined with short columnar granular cells.

(2) **Fundus Glands.**—In these glands the duct terminates in one or more tubules, lined with polyhedral cells, termed the *chief* or *central cells*. At intervals, between this layer of cells and the basement membrane, are placed larger spheroidal cells, which stain more deeply as a rule, termed the *parietal* or *oxyntic* cells. These glands are found in the fundus and body of the stomach.

(3) **Pyloric glands** are found in the pyloric portion of the stomach. These consist of a short duct, terminated in a group of short but tortuous gland tubules. These tubules are lined with short columnar or polyhedral cells, similar to the central cells of the fundus glands.

Blood-vessels.—The **arteries** of the stomach are all derived ultimately from the *cœliac artery*. The *gastric artery* arises from this trunk direct. Having reached the lesser curvature and given off an œsophageal branch, it divides into two large branches, which run, one on each side of the organ, along this curvature, and join below with two similarly-disposed arteries derived from the *right gastric* branch of the hepatic. From the two arches thus formed, four or five large branches pass to each surface of the stomach, and soon pierce the muscular coat. Along the greater curvature several smaller branches reach the stomach from the *right and left gastro-epiploic arteries*, which are branches respectively of the gastro-duodenal and the splenic, and run in the gastro-colic ligament close to its attachment to the stomach. Finally, four or five *short gastric arteries*, branches of the splenic, are distributed to the fundus of the stomach, which they reach by passing forwards between the layers of the gastro-lienal ligament. At first the arteries lie beneath the peritoneum; very soon, however, they pierce the muscular coat, which they supply, and, reaching the submucosa, break up to form a close network of vessels. From these arise numerous small branches, which enter the mucous membrane and form capillary plexuses around the glands as far as the surface.

The **veins** begin in the capillary plexuses around the glands; uniting, they form a network in the submucosa, from which arise branches that pierce the muscular coat, and finally end in the following veins: the *right gastro-epiploic*, which joins the superior mesenteric; the *left gastro-epiploic*, and four or five veins corresponding to the *short gastric arteries*, which join the splenic; the *coronary vein of the stomach*, which runs along the lesser curvature from left to right, and joins the portal vein. These veins contain numerous valves which, though competent to prevent the return of blood in the child, are rarely so in the adult.

The **lymph vessels** of the stomach arise in an extensive plexus in the mucous membrane around the gastric glands. They then join a plexus of vessels in the tela submucosa, from which

some vessels pass at intervals to join another plexus of vessels, subserous in position; piercing the muscular coats obliquely in their course. The efferent vessels pass mainly from the subserous plexus, and are arranged in three main groups, which pass in different directions, and drain three different areas of the stomach wall.

One set of vessels is connected mainly with the whole of the lesser curvature, from fundus to pylorus, and the adjacent half or two-thirds of the anterior and posterior surfaces of the stomach. These vessels pass to the superior gastric glands, along the lesser curvature, and, in company with the left gastric artery, to the cœliac glands.

The second set of vessels drains an area which includes the greater curvature below the fundus, and the adjacent portions of the anterior and posterior surfaces of the stomach. These vessels pass with the right gastro-epiploic artery to some inferior gastric glands which lie below and behind the pylorus, and thence they pass with the hepatic artery to the cœliac glands.

The third set of vessels drains the region of the fundus. The vessels from this area pass in the gastro-lienal ligament to the spleen, where they are connected with some splenic glands, and pass onwards, along the superior border of the pancreas, to the cœliac glands also.

The superior and inferior gastric glands and the splenic glands are the first glands interposed in the course of the lymph vessels. The cœliac glands form the second set.

The **nerves** are derived from the two *vagus nerves* and from the *cœliac ganglia* of the sympathetic. The vagi nerves pass through the diaphragm with the œsophagus, the left lying on its anterior, the right on its posterior aspect; in this way they reach the anterior and posterior surfaces of the stomach respectively. Here they unite with the sympathetic fibres from the cœliac plexus, which pass to the stomach with the branches of the cœliac artery. The nerve fibres, which are chiefly non-medullated, form two gangliated plexuses, those of the myenteric plexus and the submucous plexus, in the muscular and submucous coats respectively.

The development of the stomach is described with that of the intestines on pp. 52 and 1237.

INTESTINUM TENUE.

The **small intestine** is the portion of the digestive tube which is placed between the stomach and the beginning of the large intestine. It commences at the pylorus, and ends at the valvula coli by joining the large intestine. It occupies the greater portion of the abdominal cavity below the liver and stomach (Fig. 849), and is found in the umbilical, hypogastric, and both lumbar regions; also, but to a less extent, in the other regions of the abdomen, and in the pelvic cavity.

In *length*, the small intestine usually measures over 20 feet. According to Treves, it is 22½ ft. in the male, 23 in the female, whilst Jonnesco gives the average length at 24 ft. 7 ins., or 7½ metres. In form it is cylindrical, with a *diameter* varying from nearly two inches (47 mm.) in the duodenum to a little over an inch (27 mm.) at the end of the ileum; there is thus a gradual diminution in its size from the pylorus to the valvula coli.

The small intestine is relatively longer in the child than in the adult; at birth it is to the total height of the child as 7 to 1, whilst in the adult the proportion is as 4 to 1. Notwithstanding Treves' results, it is generally held that the small gut is relatively longer in the male than the female.

While the former figures, 20 to 22 feet, represent the entire length of the intestine in its most extended form after death, when muscular tonus has disappeared, it is probable that during life the length is not so great. The muscular coats, both longitudinal and circular, are more or less contracted, and probably the total length during life may be estimated as 15 to 17 feet.

In formalin-hardened bodies the small bowel rarely measures more than 12 or 13 feet in length. Similarly its diameter is often reduced in places to ½ or ¾ inch (12·5 to 18·7 mm.), although the greater part of the gut may retain its usual width: these narrow parts have apparently been fixed in a state of contraction.

The small intestine is divided into three parts (Fig. 896)—namely, the **duodenum**, constituting the first eleven inches, distinctly marked off from the rest by its fixation and the absence of a mesentery; the **intestinum jejunum** ("empty intestine") which comprises the upper two-fifths, and the **intestinum ileum** ("twisted intestine") the lower three-fifths of the remainder. The jejunum and ileum pass imperceptibly into one another, and the line of division drawn between them is artificial. Typical parts of the two—namely, the beginning of the jejunum and the end of the ileum—differ in size and in the appearance presented by their lining mucous membrane, and they can be distinguished from one another without difficulty (see p. 1200).

As the structure of the large and small intestine is similar in many particulars, it will be convenient to describe here the general structure of the intestines.

Subsequently, the peculiarities of structure of different parts will be described with the corresponding division of the tube.

Structure of the Intestines.

The wall of the intestines, like that of the stomach, is made up of four coats, named from without inwards—tunica serosa, tunica muscularis, tela submucosa, and tunica mucosa (Figs. 905 and 909).

1. **Tunica Serosa.**—The serous coat is formed of peritoneum. It varies in the extent to which it clothes the different divisions of the tube. The detailed arrangement of this coat will be given with the description of each division of the intestinal tube.

2. **Tunica Muscularis.**—This consists of unstriped muscle arranged in two layers—an outer *stratum longitudinale*, in which the fibres run longitudinally, and an inner *stratum circulare*, in which they are circularly disposed. The muscular coat is thicker in the duodenum than in any other part of the small intestine, and it gradually diminishes in thickness until the end of the ileum is reached. On the other hand, in the large intestine, it is thickest in the rectum and thinner towards the beginning of the colon.

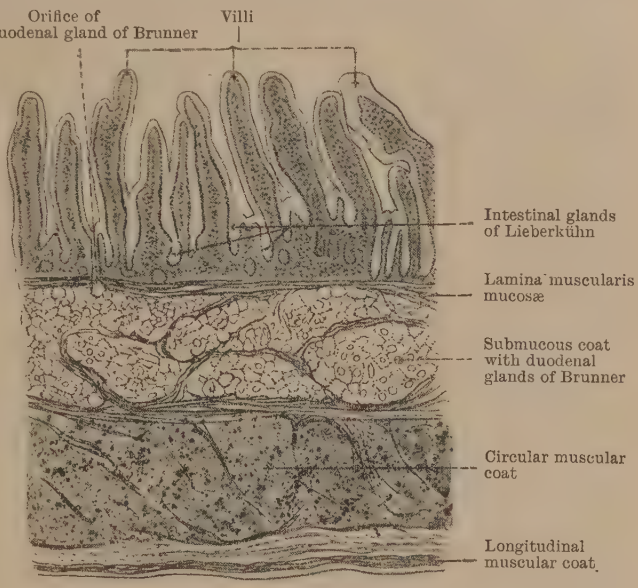

Fig. 905.—Section of Wall of Duodenum.

The **stratum longitudinale** of the muscular coat is much thinner than the underlying

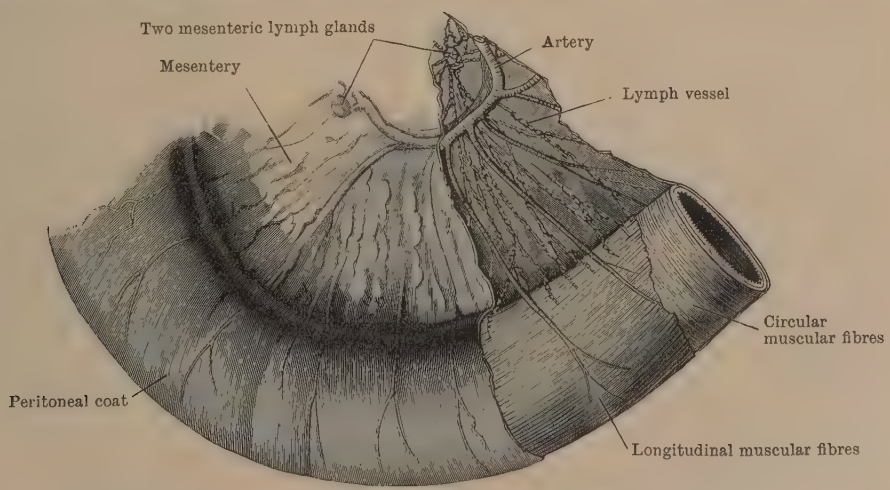

Fig. 906.—A Portion of Small Intestine, with Mesentery and Vessels.
The peritoneal coat has been removed from the right half, and the two layers of the muscular coat exposed.

stratum circulare. In the small intestine it forms a complete sheet, continuous all round the gut (Fig. 906), whilst in the greater part of the large intestine it does not form a complete coat, but is arranged as three separate longitudinal bands known as the *tæniæ coli*.

The **stratum circulare**, thicker than the longitudinal layer, is composed of bundles of muscular fibres arranged circularly round the tube (Fig. 906), and forming in all parts

a continuous sheet. Unlike the longitudinal fibres, those of the circular layer take part in the formation of the valves of the pylorus and colon.

It has recently been stated (Eben. J. Carey, *Anat. Record*, vol. xxi.) that in the small intestine these layers are not truly circular or longitudinal, but are both spiral, the inner coat forming a close and the outer a long spiral. In the inner coat one complete turn is made in every 0·5 to 1 mm. or less, while those of the outer coat which are spiral make a complete turn in every 200 to 500 mm. or more.

3. **Tela Submucosa.**—The submucous coat is a loose but strong layer of areolar tissue connecting the muscular and mucous coats, on which chiefly depends the strength of the intestinal wall. In it the vessels break up before entering the mucous coat, and it contains the *glandulæ duodenales* (*Brunneri*) (Fig. 905). In both small and large intestines, the bases of the solitary lymph nodules lie in it (Fig. 910).

4. **Tunica Mucosa.**—The mucous membrane is composed (Fig. 905) of the following parts: (1) A layer of striated, columnar, epithelial cells, resting on a basement membrane. Outside this lies (2) a layer of retiform tissue, containing a considerable number of scattered lymph cells. This layer is limited towards the tela submucosa by (3) an extremely thin sheet of unstriped muscle, the **lamina muscularis mucosæ**, which is not visible to the naked eye. The mucous membrane is very vascular, particularly in the small intestine. It is thicker in the duodenum than in the jejunum, and thicker in the jejunum than in the ileum.

Throughout both the small and large intestines the mucous membrane contains (4) innumerable (small microscopic) tubular glands, the **glandulæ intestinales** [Lieberkühni]. In shape they are minute straight tubes. Their mouths open on the free surface of the mucous membrane: their closed ends lie in the deeper part of the mucous coat, and their cavities are lined with columnar epithelium. In the small intestine they open on the surface between the bases of the villi, and in the large gut their orifices are found all over the surface of the non-villous mucous membrane.

Nerves.—The intestine has a large supply of nerves belonging to the sympathetic system, which accompany the vessels to the wall of the intestine, and are distributed to the vessels and to the walls.

The nerves, derived from the cœliac and mesenteric plexuses, and connected also with the right vagus, anastomose in the subserous tissue, traverse the outer muscular coat, and between the muscle coats form an extensive plexus, composed of interlacing fibres and ganglion cells, termed the myenteric plexus of Auerbach.

From this plexus, branches pierce the inner muscular coat and pass to the tela submucosa, and again form a plexus, known as the plexus of Meissner, from which branches pass to the lamina muscularis mucosæ, to the muscle tissue of the villi, and to the mucosa.

Keith compares the tissue of Auerbach's plexus to the nodal tissue of the heart, and describes special regions in which it is most highly developed, which he considers may act as "nodal points" for peristalsis.

The afferent nerve supply of the intestine is from the sympathetic system, and hence the whole intestine except the anal canal is quite insensitive to stimuli which in other parts would give rise to pain. Strong contraction, however, of the muscle coats causes severe pain, which is referred not to the intestine but to some portion of the abdominal wall.

Vessels.—The vessels, on reaching the intestine, bifurcate, giving a branch to each side of the gut. These latter run transversely round the intestines, at first under the peritoneal coat; soon, however, they pierce the muscular coat and form a plexus in the submucosa, from which numerous branches pass to the mucous membrane, where some form plexuses around the intestinal glands whilst others pass to the villi. The **veins** are similarly disposed, and the blood from the whole of the small intestine beyond the duodenum is returned by the superior mesenteric vein, which joins with the splenic to form the portal vein.

The **lymph vessels** of the small intestine (known as lacteals) begin in the villi, and also as lymph sinuses surrounding the bases of the solitary nodules; a large plexus is formed in the submucosa, a second between the two layers of the muscular coat, and a third beneath the peritoneum. The vessels from all these pass up in the mesentery, being connected on the way with the numerous (from 40 to 150) **mesenteric glands**, and finally unite to form the **truncus intestinalis**, which opens into the cisterna chyli.

Certain special developments of the mucous coat, found in particular regions of the intestinal tube, must next be considered: these are the (1) villi intestinales; (2) plicæ circulares [Kerkringi] (O.T. valvulæ conniventes); (3) noduli lymphatici solitarii (O.T. solitary glands); and (4) noduli lymphatici aggregati [Peyeri] (O.T. Peyer's patches).

Villi Intestinales.—The mucous membrane of all parts of the small intestine presents a soft, velvety, or fleecy internal surface (Fig. 908, B); this is due to the presence of an enormous number of minute processes, known as villi.

They are minute, cylindrical, or finger-like projections of the tunica mucosa (Fig. 907) about $\frac{1}{20}$th to $\frac{1}{50}$th of an inch (0·2 to 1·2 mm.) in height, barely visible to the naked eye. Beginning at the edge of the pyloric valve, they are broad but short in the duodenum, and grow narrower as they are followed down through the intestine to the valvula coli, at the edge of which they cease. They are found, not only on the general surface of the mucous membrane, but also upon the plicæ circulares, and, while they are not present over the solitary lymph nodules, they are found in the intervals between the individual nodules of the aggregated nodules.

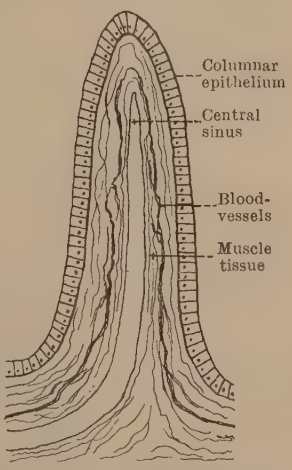

FIG. 907.—STRUCTURE OF A VILLUS.

Structure of the Villi.—Each villus is covered by a layer of columnar cells, set upon a basement membrane, and under this is a fine layer of longitudinal non-striated muscle, continuous with the lamina muscularis mucosæ of the intestine.

In the interior of each villus is a *central sinus*, a space lined with endothelium, continuous with the lymphatic vessels (chyle vessels) of the mucosa. There may be several such lymph spaces within the larger villi.

A network of blood-vessels lies between the epithelium and the central sinus.

Dilatation of these vessels causes enlargement of the villus, while contraction of the muscle layer diminishes its height and serves to assist in emptying the central sinus into the lymphatic or chyle channels.

The villi thus play an important part in the absorption of the products of digestion.

Plicæ Circulares [Kerkringi].—When the intestine is empty and contracted, its mucous membrane is thrown into folds which disappear on distension. In addition to these, there are in certain portions of the small intestine a series of large, permanent folds, known as *plicæ circulares* of Kerkring (Fig. 908). These are usually more or less crescentic in shape, and resemble a series of closely placed shelves running transversely around the gut. They rarely form more than two-thirds of a circle; sometimes, however, they present a spiral arrangement, the spiral extending little more than once round the tube, as a rule. Occasionally they bifurcate at one or both ends; sometimes, too, short irregularly directed branches pass off from them. They are usually about 2 to 3 inches (5 to 7·5 cm.) in length, and their height, that is their projection into the cavity, may be as much as $\frac{1}{3}$rd of an inch (8 mm.), whilst in thickness, as seen when cut across, they measure about $\frac{1}{8}$th inch (3 mm.).

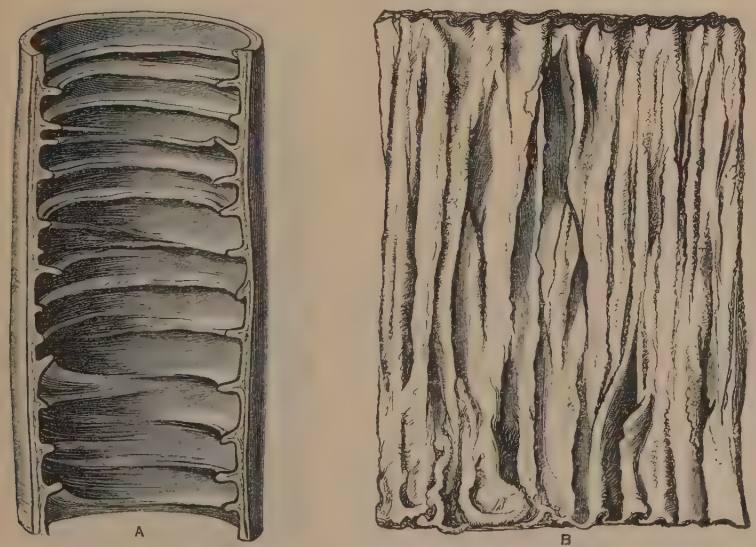

FIG. 908.—PLICÆ CIRCULARES (natural size).

A, as seen in a portion of jejunum which has been filled with alcohol and hardened; B, a portion of fresh intestine spread out under water.

They are folds of the tunica mucosa, with a prolongation from the tela sub-

mucosa and they increase the amount of surface available for secretion and absorption.

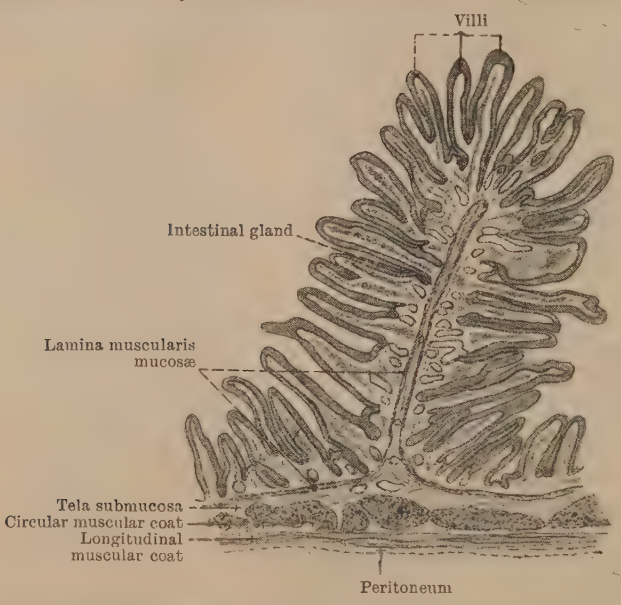

FIG. 909.—TRANSVERSE SECTION OF A PLICA CIRCULARIS AND WALL OF SMALL INTESTINE.

Plicæ circulares are not found in the upper part of the duodenum. They begin at a distance of from 1 to 2 inches (2·5 to 5 cm.) beyond the pylorus. At first they are small, irregular, and scattered; but they are larger lower down, and at the opening of the bile duct (4 inches from the pylorus) they are distinct and prominent. In the rest of the duodenum, and in the superior half of the jejunum, they are highly developed, being large, broad, and closely set. In the inferior half of the jejunum they become gradually smaller and fewer. In the ileum they become still smaller and more irregular, and, as a rule, they practically cease a little below its middle, though patches of plicæ circulares, much reduced in size, can be traced to within a short distance of the valvula coli.

Noduli Lymphatici Solitarii.—The solitary lymph nodules are minute masses of lymph tissue, opaque and of a whitish colour, which project on the surface of the mucous membrane throughout the whole length of both the small and large intestines.

Isolated lymph cells are found in abundance scattered through the connective-tissue layer of the intestinal mucous membrane generally; in places these cells are gathered together to form little nodules, supported by a framework of retiform tissue, and surrounded by a lymph space which communicates below with the lymph vessels of the tela submucosa. Such a collection of lymph cells constitutes a solitary nodule. They are usually of a rounded or oval shape (Fig. 910), the wide end resting in the tela submucosa, the nodule itself piercing the lamina muscularis mucosæ, and the narrow end projecting slightly above the general surface of the mucous membrane. In size they vary from $\frac{1}{40}$th to $\frac{1}{8}$th of an inch (·6 to 3·0 mm.), but their average bulk is about that of a small grain of sago, to which they bear some resemblance.

FIG. 910.—NODULI LYMPHATICI AGGREGATI and SOLITARII, from intestine of child two years old (natural size).

Near the lower border are seen a few small patches made up of two or three lymph nodules; they are marked "intermediate form."

They are present in the whole digestive tube, but are particularly abundant in the vermiform process and the cæcum.

Noduli Lymphatici Aggregati.—These lymph nodules (Peyer) consist of a large number of minute lymph nodules grouped closely together and forming a slightly elevated area, usually of an oblong form, on the surface of the mucous membrane (Fig. 910). In length they vary from half an inch (12

mm.), or less, to three or four inches (100 mm.), and in width they commonly measure from a third to half an inch (8 to 12 mm.). Their number is variable, but in the average condition about 20 or 30 are found. They are best marked in young subjects, where they form considerable elevations above the general surface, and may be as many as 45 in number. After middle life they atrophy, and in old age, although usually present, they are indistinct, occasionally being marked by little more than a dark discoloration of the mucous membrane. They are invariably situated along the surface of the intestine opposite the line of mesenteric attachment, with their long axis corresponding to that of the bowel. Consequently, in order to display them, the tube must be slit up along its attached or mesenteric border.

These aggregated nodules are entirely confined to the small intestine, being largest and most numerous in the ileum, particularly in its inferior part, where they usually assume an oblong shape; in the inferior half of the jejunum they are small, circular, and few in number; in its superior part they are much less numerous; and in the duodenum only few can be found.

The plicæ circulares stop at the margins of the aggregated nodules, and are not continued across them; but villi are found on the surface of the aggregated nodules, in the intervals between the individual lymph nodules.

The chief bowel lesion in typhoid fever is found in these aggregated and in the solitary nodules.

When the surface of one of these nodules from a child's intestine (in which these structures are particularly well developed) is carefully examined, it is seen to be made up, not of a series of separate, rounded nodules grouped together, but rather of a number of wavy, irregular, and branching ridges connected with one another by cross branches (Fig. 910), the whole recalling in miniature the appearance of a raised map of a very mountainous district in which the chief chains run irregular courses, and are joined to one another by connecting ridges.

Small patches, intermediate in form between solitary and aggregated nodules, and consisting of two or three lymph nodules, are also usually present.

DUODENUM.

The **duodenum** is the first part of the small intestine, and differs from the rest of that tube in having no mesentery, and hence it is fixed to the posterior abdominal wall. The ducts of the liver and pancreas open into it, and some special glands are found in its wall, known as the *duodenal glands of Brunner*.

Shape and Divisions.—The duodenum begins at the pylorus, about the level of the first lumbar vertebra, and ends at the left side of the first or second lumbar vertebra (Fig. 911).

It forms an irregular horseshoe-shaped curve, with the opening directed upwards and to the left, and the ends reaching to within about two inches of one another. Within the concavity of the curve the head of the pancreas is placed. It is divided into three main parts, namely: (1) The **pars superior**, which begins at the pylorus, passes posteriorly and to the right beneath the liver, and ends at the neck of the gall-bladder by turning down, forming the *flexura superior*, and joining (2) the **pars descendens**. This begins at the neck of the gall-bladder, runs down on the posterior abdominal wall, on the right of the vertebral column, behind the transverse colon (Fig. 912), and ends opposite the third or fourth lumbar vertebra. There it turns to the left, and passes into (3) the **pars inferior**. This portion at first runs more or less transversely to the left, across the vena cava, aorta, and vertebral column (*pars horizontalis*), and then ascends as far as the inferior surface of the pancreas (*pars ascendens*). There, at the level of the first or second lumbar vertebra, it bends abruptly forwards, forming the **duodeno-jejunal flexure** (Fig. 912), and passes into the jejunum. The junction of the pars descendens and pars inferior constitutes the *flexura inferior*.

The three parts of the duodenum do not all lie in the same plane; for, whilst its greater part is placed in a frontal plane, the superior part, and the commencement and termination of the inferior part, lie more in a sagittal plane (Fig. 912).

Position and Size.—As a rule, a little more than half of the duodenum lies in the epigastrium; the remainder—namely, about the inferior third of the descending

portion and the adjoining two-thirds of the inferior portion—is placed in the umbilical region. With the exception of the terminal ascending portion of the third part, the whole of the duodenum lies to the right of the median plane.

Its length is usuallylabout 11 inches (27·5 cm.), its first portion being the shortest

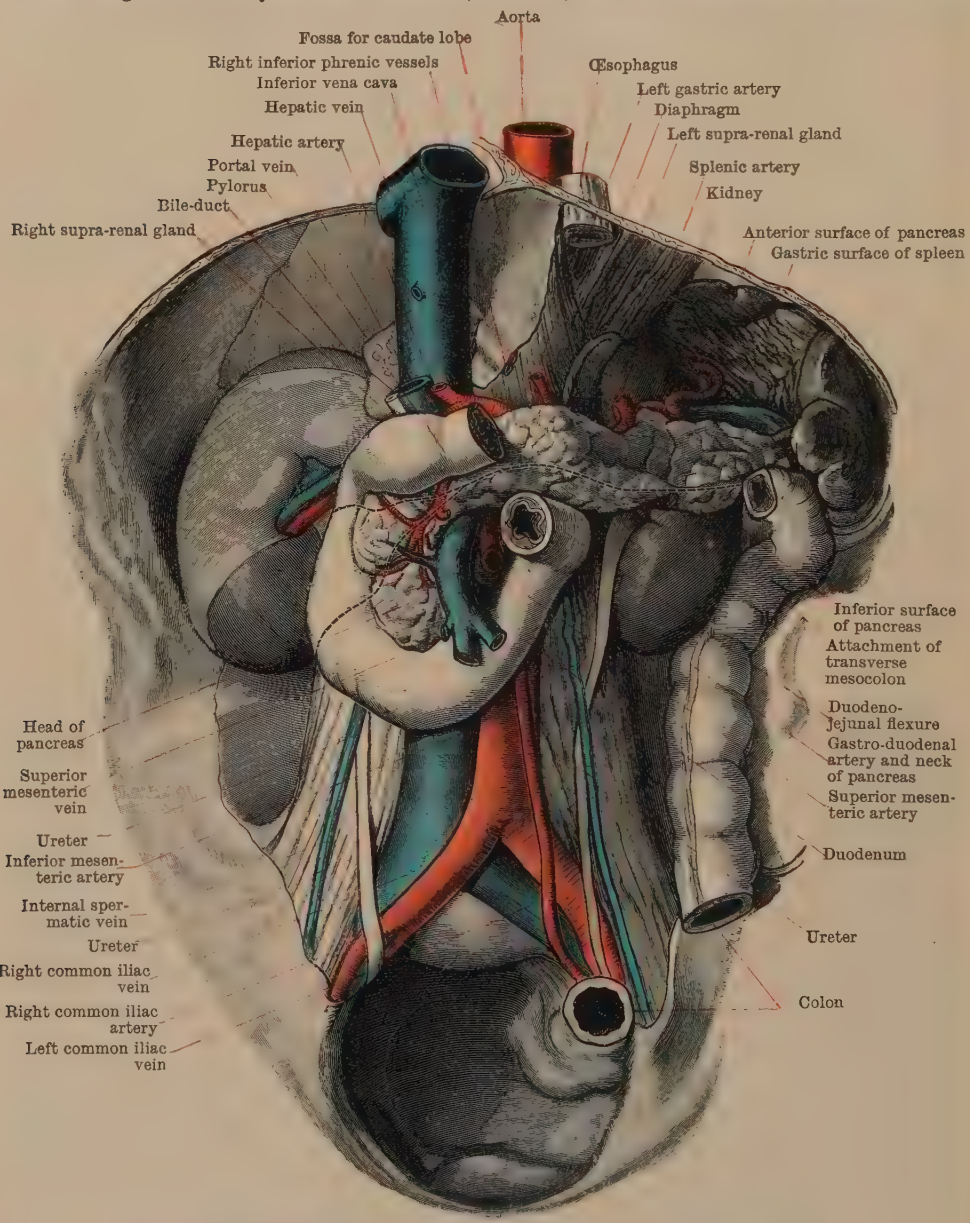

FIG. 911.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney, and the fossa for the caudate lobe. When the liver was taken out, the vena cava was left behind. The stomach bed is well shown. (From a body hardened by injection of chromic acid.)

and its third portion the longest. Its diameter varies considerably, and may be stated to average about 1½ inches when empty, but it may be two inches or more in diameter when distended.

Pars Superior.—The length of the superior part varies from about 1½ to 2 inches (3·7 to 5·0 cm.), and is said to be greater when the stomach is empty than when distended.

Its relations are as follows: It forms the inferior boundary of the foramen epiploicum, and, above that foramen, it is in relation to the caudate process of the liver, while the quadrate lobe of the liver hangs downwards over it and to the right. The hepatic artery is in contact for a short distance with the superior border. Below, it rests on the head and neck of the pancreas. The portal vein, gastro-duodenal artery, and the bile duct lie in contact with it on the left side, and behind them the duodenum comes into contact with the right aspect of the inferior vena cava. The superior pancreatico-duodenal and the right gastro-epiploic vessels pass forwards below its inferior margin.

Its *peritoneal relations* are similar to those of the pyloric end of the stomach for about an inch. It is therefore at first invested by peritoneum on the right and left aspects, and the peritoneum passes upwards from its superior border as the right portion of the lesser omentum,

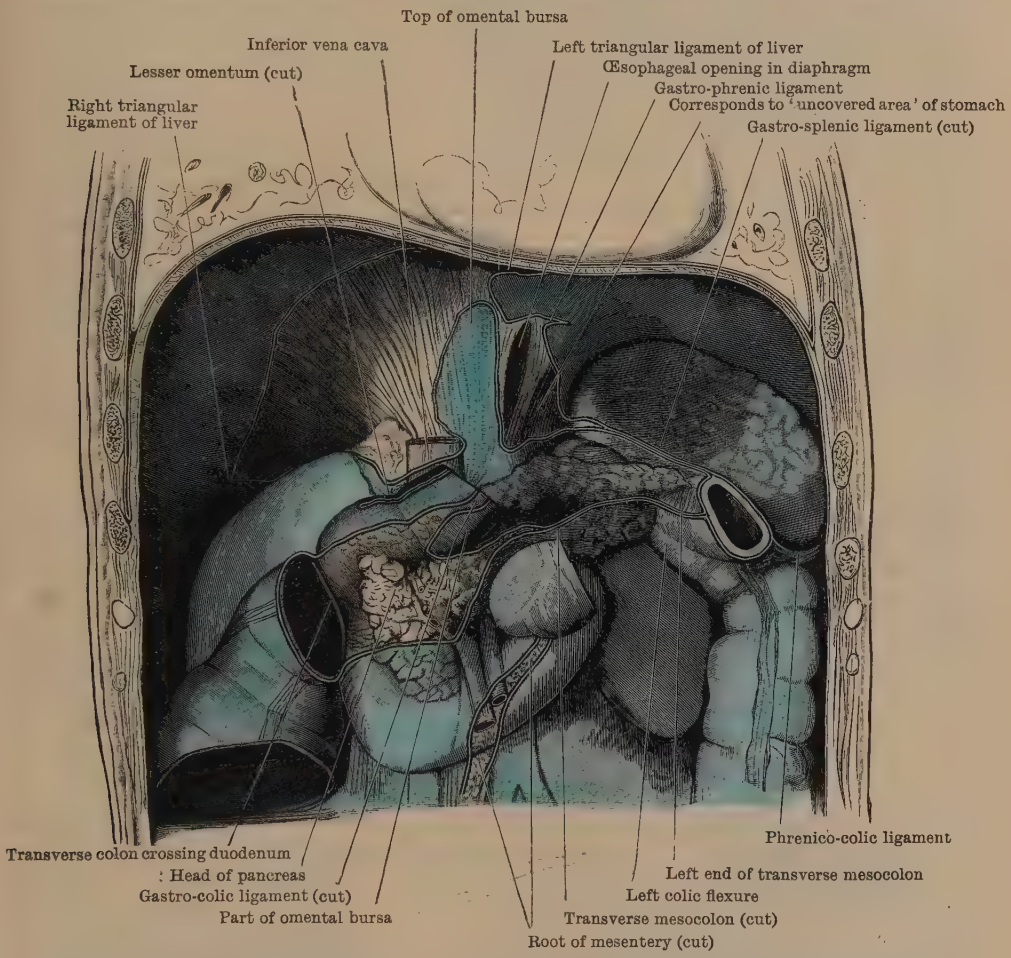

FIG. 912.—THE PERITONEAL RELATIONS OF THE DUODENUM, PANCREAS, SPLEEN, KIDNEYS, ETC.

From a body hardened by injections of formalin. When the liver, stomach, and intestines were removed the lines of the peritoneal reflections were carefully preserved. The peritoneum is coloured blue.

forming the *hepato-duodenal ligament*, while from its inferior border the descending folds of the peritoneum pass downwards. The peritoneum is reflected from off the left surface on to the pancreas and abdominal wall, and forms a fold known as the *right gastro-pancreatic fold*, while the peritoneal covering of the right side is continued onwards along the whole of this part of the duodenum.

Pars Descendens.—The **descending part** in length measures 3½ or 4 inches (8·7 to 10 cm.).

Its relations are as follows: It lies on the right of the vertebral column and the inferior vena cava, from the first to the third or fourth lumbar vertebra, and is anterior to the pelvis of the right kidney, the right renal vessels, and ureter, and also, to a varying extent, the front of the right kidney itself; while, below the level of those structures, it rests upon the psoas major muscle.

The lateral aspect is in contact with the sloping inferior surfaces of the liver in its superior part, and with the right flexure of the colon below.

Peritoneal Relations.—The anterior aspect is covered by peritoneum, except about its middle,

where the root of the transverse mesocolon crosses the duodenum. Not infrequently, the transverse colon has no mesentery, but is itself in direct contact with the wall of the duodenum. In other cases, the colon is in contact with the peritoneal surface of the duodenum, below the line of reflection of the transverse mesocolon.

The head of the pancreas is in contact with its concave left margin, and occasionally overlaps it anteriorly and posteriorly; and along the margin of the pancreas, both anteriorly and posteriorly, are branches of the superior and inferior pancreatico-duodenal vessels, the veins often forming a dense network on the posterior aspect.

The bile duct, after passing down behind the superior part of the duodenum, descends between the head of the pancreas and the descending part, nearly as far as its middle; there it is joined by the pancreatic duct, and the two, piercing the wall of the duodenum obliquely, open by a common orifice on its inner aspect, about 3 to 4 inches (8·7 to 10 cm.) beyond the pylorus.

Pars Inferior.—The horizontal portion of the **inferior part** runs more or less transversely to the left across the inferior vena cava (Fig. 911) for one or two inches, and the ascending part passes very obliquely, or even vertically, upwards in front of the aorta and left psoas major muscle. Finally, having reached the inferior surface of the pancreas, it bends forwards, and passes into the jejunum.

Anteriorly, the pars inferior is crossed (about the junction of its two divisions) by the superior mesenteric vessels, and also by the root of the mesentery (Fig. 912). On each side of this it is covered by coils of small intestine. *Posteriorly*, the pars horizontalis lies across the vena cava inferior; the pars ascendens lies on the aorta, the left renal vein and occasionally also the artery, and the left psoas major muscle, all of which separate it from the vertebral column. *Above*, it is closely applied in its whole extent to the head of the pancreas. The *left side* of the pars ascendens, which is free, lies in contact with some coils of the small intestine.

Peritoneal Relations.—The inferior part of the duodenum is covered by peritoneum on its anterior surface throughout, except where it is crossed by the superior mesenteric vessels and the root of the mesentery, which contains these vessels (Fig. 912). In addition, its ascending part is also clothed by this membrane on its left side.

The attachment of the root of the mesentery begins, above, quite close to the duodeno-jejunal flexure, on the front of the duodenum; thence it runs down on the anterior aspect of the ascending part, and finally leaves the duodenum about the union of the two divisions of its third portion.

Duodenal Fossæ.—In the neighbourhood of the pars ascendens are found three well-known fossæ of the peritoneum which are of some surgical interest; they are the superior and inferior duodenal and the paraduodenal fossæ (Fig. 913). Other rarer forms are occasionally present.

When the ascending part of the duodenum is drawn over to the right, one or two triangular folds of peritoneum will generally be found passing from the duodenum to the abdominal wall. Each fold at one end is attached to the duodenum, at the other to the parietal peritoneum at the left of the duodenum, whilst the third margin is free, and bounds the opening of a small pouch which lies between the folds, the *recessus duodeno-jejunalis*. Of these folds, the *upper* is situated near the termination of the duodenum, with its free margin directed down. It sometimes contains between its two layers the termination of the inferior mesenteric vein. Behind it lies a prolongation from the recessus duodeno-jejunalis termed the **superior duodenal fossa**. Its opening looks downwards, and will usually admit the tip of a finger (Fig. 913). The second fold is placed lower down. Its free border is directed upwards, as is the mouth of the **inferior duodenal fossa**, which lies behind it. This latter is larger and more constant than the superior duodenal fossa, and is present in 75 per cent of bodies, whilst the superior is present in 50 per cent (Jonnesco).

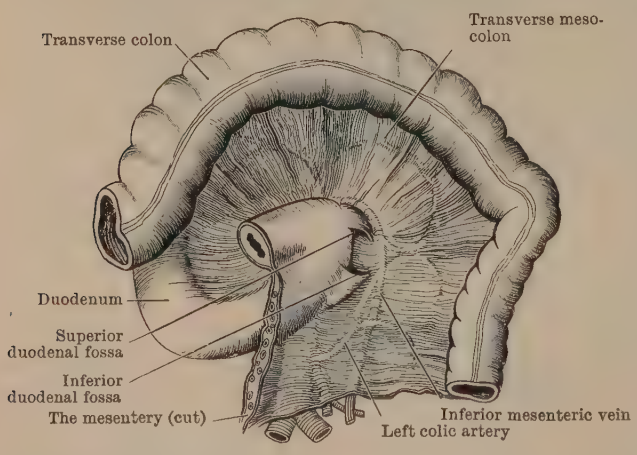

FIG. 913.—THE DUODENAL FOSSÆ AND FOLDS.

The transverse colon and mesocolon have been thrown up, and the mesentery has been turned to the right and cut. The paraduodenal fossa (of Landzert) is situated to the medial side of the inferior mesenteric vein, between it and the terminal part of the duodenum. It is not shown in the illustration.

Paraduodenal Fossa (fossa of Landzert).—This fossa, which is seen best in the

infant, is placed some distance to the left of the ascending part of the duodenum. It is produced by the inferior mesenteric vein raising up a fold of peritoneum, as it runs medially along the side of the fossa, and then above it (see Fig. 913, where the vein, but not the fossa, is shown). It is limited below by a special fold (the mesenterico-mesocolic fold). According to Moynihan, this is the only fossa to the left of the duodenum capable of developing into the sac of a hernia; and when this occurs, the inferior mesenteric vein always lies in the anterior margin of the orifice of the sac (accompanied for some distance by the ascending branch of the left colic artery).

Accessory pancreatic duct
Papilla duodeni, with hood-like fold and opening of ducts
Plica circularis
Plica longitudinalis duodeni

Fig. 914.—Interior of a Portion of the Pars Descendens Duodeni (viewed from the front).

Peritoneal Relations of the Duodenum.—Whilst the relations of the peritoneum to the second and third portions of the duodenum are usually described as in the foregoing account, it should perhaps be pointed out, that it is not really the front, but the right half of the circumference of the descending portion which has a serous coat. Similarly, it is the inferior and anterior half of the circumference of the horizontal portion of the inferior part which is clothed by peritoneum, whilst considerably more than half of the circumference of its ascending portion is covered; for the peritoneum forms a fold running in behind this portion, in addition to covering its left side and half its anterior aspect.

Interior of Duodenum.—No plicæ circulares are found in the duodenum for an inch or two beyond the pylorus. They begin as low, scattered, and irregular folds; further down, they gradually become larger, more regular, and more numerous; and at the middle of the descending part they have attained a considerable development. In the inferior part of the duodenum the folds are large, prominent, and closely set.

On the postero-medial wall of the descending portion, about its middle—namely, 3½ or 4 inches (8·7 to 10 cm.) beyond the pylorus—is seen a prominent papilla, on which the bile and pancreatic ducts open by a common orifice (Fig. 914) known as the **papilla duodeni** (Santorini).

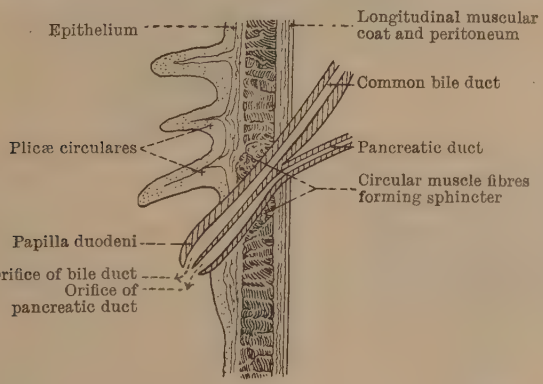

Fig. 915.—Diagrammatic Section of Wall of Duodenum through Papilla.

The papilla duodeni is placed beneath, and protected by, a prominent, hood-like plica circularis, which is situated immediately above it. From its lower margin a firm ridge of the mucous membrane, the *plica longitudinalis duodeni*, descends for a considerable distance, and acts as a frenum, which fixes the papilla and directs its apex somewhat downwards (Fig. 914). The papilla is prominent, and nipple or dome-shaped, and at its summit is placed the small orifice, which will usually admit the point of a pencil; the whole bears a close resemblance to the nozzle of a perfume-spray.

Nearly an inch higher up, and invariably on the ventral side of the papilla (sometimes as much as ½ to ¾ inch distant), is seen a second and smaller papilla, the *caruncula minor* of Santorini, at the point of which is placed the very small orifice of the accessory pancreatic duct. This second papilla seems to be constantly present, although sometimes so small that it may easily escape detection unless carefully sought for. When well developed, it may have a hood-like plica circularis and a little frenulum, like those of the bile papilla.

Structure of the Duodenum.—The **tunica serosa**, which is incomplete, has already been described in detail, in connexion with each part of the duodenum.

The **tunica muscularis** is well developed, and is pierced by the bile and pancreatic ducts.

As the united bile and pancreatic ducts traverse the muscular walls, they are surrounded by some fibres from these coats which form a sphincter apparatus, and extend into the papilla.

The **tela submucosa** differs from that of the rest of the small intestine, in that it contains, especially in the superior half of the duodenum, the **glandulæ duodenales** [Brunneri]. These are small acino-tubular glands, closely resembling the pyloric glands of the stomach; they lie in the submucous coat, and send their ducts through the muscularis mucosæ to open on the surface between the glandulæ intestinales, or sometimes into these glands themselves (Fig. 905). To naked-eye examination they are small, round, or flattened masses of a reddish-gray colour, varying in size from $\frac{1}{60}$th to $\frac{1}{12}$th of an inch in diameter (·5 to 2·0 mm.). They form an almost continuous layer as far as the opening of the bile duct; beyond this they diminish progressively, and completely disappear near the duodeno-jejunal flexure.

The **tunica mucosa**, which is thicker in the duodenum than in any other part of the small intestine, is covered throughout with broad, short villi.

Various Forms of Duodenum.—Three different types of duodenum have been described—(1) The **annular**, in which the curves separating the various parts are open, and the two extremities come fairly close to one another. (2) The **U-shaped**, in which the horizontal part of the inferior part is very long, and the ascending part is nearly vertical; and (3) the **V-shaped** duodenum, in which the horizontal portion of the inferior part is very short or absent.

Vessels and Nerves.—The duodenum receives its blood from the superior and inferior pancreatico-duodenal arteries, branches of the gastro-duodenal and superior mesenteric arteries respectively. The blood is returned by the corresponding veins, the superior of which opens into the superior mesenteric, and the inferior into the beginning of the portal vein.

The **lymph vessels** of the duodenum follow for the most part the course of the blood-vessels.

From the anterior surface, lymph vessels pass along the course of the inferior pancreatico-duodenal artery, and communicate with lymph glands found along the course of that vessel. Thence they pass to the inferior cœliac glands, beside the origin of the superior mesenteric artery.

The vessels from the posterior aspect accompany the superior pancreatico-duodenal artery, communicate with the inferior gastric glands, and terminate in the cœliac glands.

The **nerves** come from the cœliac and superior mesenteric plexuses of the sympathetic.

Flexura Duodenojejunalis.—When the ascending part of the duodenum reaches the inferior surface of the pancreas, at a point opposite the left side of the first or second lumbar vertebra, it turns abruptly forwards, downwards, and to the left, and passes into the jejunum. This abrupt bend is known as the **duodeno-jejunal flexure.** Unlike the rest of the duodenum, which is subject to considerable variations in position in different individuals, the duodeno-jejunal flexure is fixed by a thin band of unstriped muscle, which is attached above to the strong connective tissue around the cœliac artery, as well as to the left crus of the diaphragm. This band passes posterior to the pancreas, and inferiorly it joins the muscular coat of the duodenum at the flexure. It is known as the **m. suspensorius duodeni.**

The duodeno-jejunal flexure is occasionally directed to the right, and it lies at a variable distance from the root of the transverse mesocolon. When the attachment of the transverse mesocolon is low, the duodeno-jejunal flexure is in contact with it.

Duodenal Pouches or Diverticula.—Occasional diverticula are found passing from the duodenal wall in different directions. Such diverticula may be hernial protrusions of the mucous and submucous coats through the muscular wall, termed false diverticula, or they may be "true" diverticula, in which all the coats are represented.

They are usually situated on the aspect of the duodenum which is in contact with the pancreas, and frequently in the neighbourhood of the orifice of the bile duct.

Some of these appear to be due to the pressure from the interior of the duodenum, while others, and the majority of the true diverticula, are rather congenital in origin, and are possibly associated with the diverticula which give rise to the liver and pancreas.

HEPAR.

The **liver** is the large glandular organ which secretes the fluid called bile (fel). It occupies the superior and mainly the right portion of the abdominal cavity, and lies immediately below the diaphragm.

Its secretion is conveyed by the hepatic ducts and the bile duct to the duodenum. With the bile duct there is connected a pear-shaped diverticulum, the gall-bladder (vesica fellea), which lies in contact with the liver, and which serves apparently for the temporary storage of bile. Bile is a clear, yellowish-green, or brown fluid, of bitter taste.

In addition to secreting bile, the liver plays an important part in the metabolism of both the carbohydrate and nitrogenous materials absorbed from the

intestine which are conveyed to it by the portal vein, and it also has to do with the production and the destruction of some of the blood cells.

Physical Characters.—The liver is a large irregularly shaped mass, of a reddish-brown colour, soft and pliant to the touch, somewhat readily lacerated, and highly vascular.

It is of uniform consistence throughout, and little of its internal structure can be made out by naked-eye examination. If, however, a torn surface is examined, the liver tissue is seen to be somewhat granular. Under the investing peritoneum the surface is somewhat mottled.

This mottled or granular appearance is due to the lobules (**lobuli hepatis**) of which the liver is composed. Each lobule is a small irregular or polygonal area, measuring from $\frac{1}{25}$th to $\frac{1}{12}$th of an inch in diameter, or 1 to 2 mm., with a partial covering of fine connective tissue, forming a delicate stroma.

In the adult, the liver weighs from 3 to $3\frac{1}{4}$ pounds, or about $\frac{1}{50}$th of the body

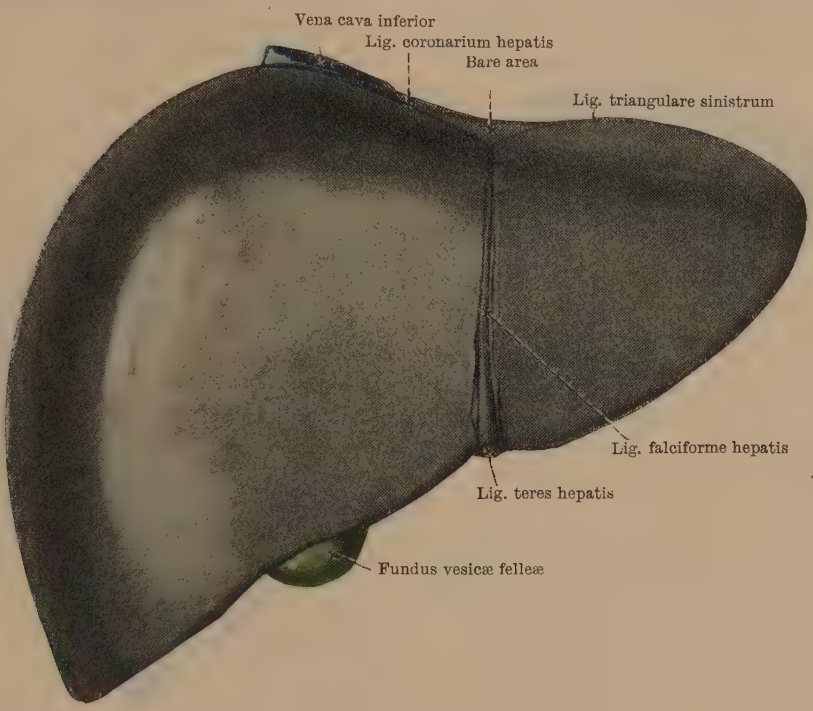

Fig. 916.—Liver viewed from the front.

weight, and it is somewhat heavier in the male than in the female, its weight in the former being from 50 to 55 ounces and in the latter 43 to 48 ounces. The ratio to the body weight is the same in both sexes. In the fœtus and child it is relatively very large and heavy. At birth it occupies the greater part of the abdominal cavity, and constitutes from $\frac{1}{20}$th to $\frac{1}{18}$th of the body weight. In the young fœtus the ratio is even larger.

The average size of the liver may be briefly expressed as follows: It measures in the transverse direction about seven inches (17·5 cm.); in the vertical, six to seven inches (15 to 17·5 cm.); and in the antero-posterior, on the right side where greatest, about six inches (15 cm.). Its greatest width, measured obliquely from side to side along the inferior or visceral surface, is ten inches (25 cm.).

The liver is capable of being greatly distended by fluid forced into its blood-vessels. Its surface then becomes tense, and the consistence of the whole organ becomes much firmer.

Shape.—If the liver is hardened *in situ* and then removed from the body, it will be found to present a form which is fairly constant, but which is modified by the shape and size of the adjacent viscera, and hence shows minor variations in different individuals.

If the liver has not been hardened, it does not retain, after removal, the shape and form which it had when it lay in the abdomen, but tends to collapse into a flattened cake-like mass. The description of the shape, surfaces, and borders given below is drawn from examination of specimens hardened *in situ*.

The liver possesses three principal surfaces, a superior, a posterior, and an inferior or visceral.

The **facies superior** is smooth and rounded, and in contact with the diaphragm and anterior abdominal wall.

The attachment of a sagittal fold of peritoneum, the falciform ligament, divides it into right and left portions, termed right and left lobes.

The superior surface may be further divided into three areas, a superior, an anterior, and a right, following the general direction of these portions of the surface, but they are not clearly marked off from one another by borders.

The **superior area** of the **superior surface** lies in contact with the roof of the abdomen; it is convex on each side, and depressed near the median plane. The two convexities, of which the

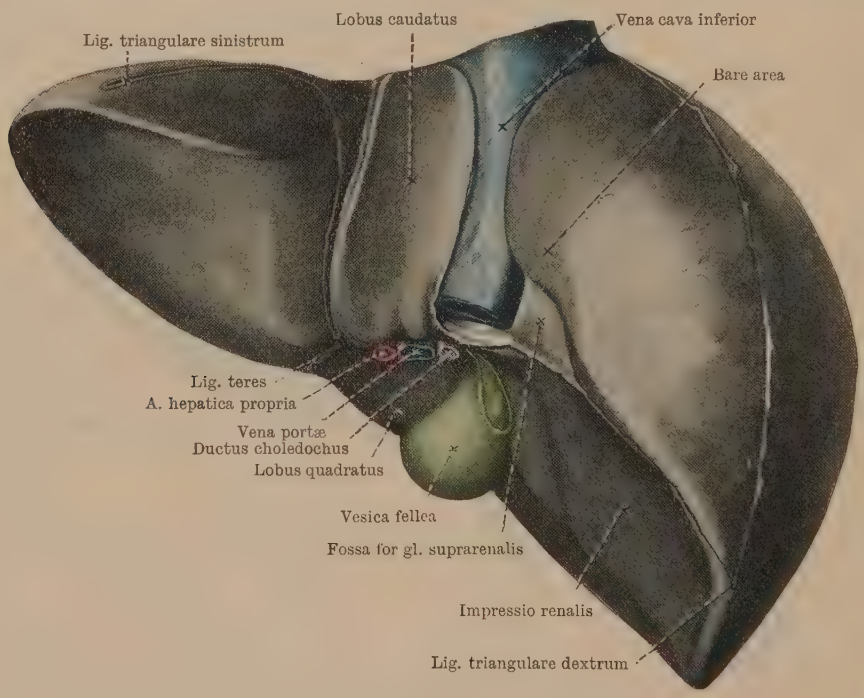

FIG. 917.—THE LIVER VIEWED FROM BEHIND.

right is the more prominent, fit into the two cupolæ of the diaphragm; whilst the central depression, *depressio cardiaca*, corresponds to the position of the heart.

The **anterior area** of the **superior surface** is triangular in shape, and after death is usually flattened, owing to the falling in of the anterior abdominal wall. In part it lies in contact with the diaphragm, which separates it from the rib-cartilages on each side, but at the subcostal triangle it comes into direct relation with the anterior wall of the abdomen, for a distance usually of two or three inches below the xiphi-sternal articulation.

The anterior passes gradually into the upper and right areas, but it is distinctly separated from the visceral surface by the sharp anterior margin of the organ. The umbilical notch is often continued upwards for some distance on the surface as a slit-like fissure.

The **right area** of the **superior surface** is convex and extensive, and lies in contact with the diaphragm, which separates it from the inner surface of the lower ribs, and also, above, from the inferior margin of the lung and pleura. Though sharply marked off by an inferior margin from the visceral surface, it passes without distinct limits into the other areas of the parietal surface. It is completely covered by peritoneum.

The **facies inferior** (visceral surface) is directed obliquely downwards and posteriorly, is uneven and concave, and in contact with a number of the abdominal viscera, especially the right kidney, stomach, duodenum, and colon. Its general

configuration is influenced to a marked degree by the shape and position of these organs.

The superior and inferior surfaces are marked off from one another in front by a sharp edge, the **margo anterior**, and behind by a wide area, the **posterior surface** (facies posterior). The anterior border is thin and sharp, and usually, but not invariably, presents one or two notches, one the **incisura umbilicalis**, the more constant of the two (Fig. 918), situated at the anterior end of the cleft on the inferior surface, known as the **fossa sagittalis sinistra** lodges at the upper part of the ligamentum teres hepatis. It is usually placed from one to two inches (2·5 to 5·0 cm.) to the right of the median plane. The second notch, less frequently present, contains the fundus of the gall-bladder, and is called the **incisura vesicæ felleæ.**

To the left extremity the margo anterior is continued along the margin of the left lobe, and ends at a groove on the posterior surface, termed the **impressio œsophagea,** in which lies the œsophagus.

The **facies posterior** (Fig. 917), directed backwards, is in contact with the structures of the superior portion of the posterior abdominal wall. It is deeply indented by the projecting vertebral column, and it is nearly flat in the vertical axis.

Fissures and Lobes.—In many animals the liver is divided by deep clefts into several partly or wholly detached masses, known as lobes.

In man such clefts do not as a rule extend deeply into the substance, but on the inferior and posterior surface are found several surface fissures, which partly divide these areas into lobes.

The chief of these are:—

(1) **Porta Hepatis.**—The **gate of the liver** (O.T. **portal** or **transverse fissure**) is the equivalent in the liver of the hilum of other glands. It is a slit-like depression, where the vessels enter the gland, and whence the ducts emerge.

It is placed on the inferior surface, runs transversely from side to side, and measures about 2 to 2½ inches in length. It is bounded anteriorly and posteriorly by prominent margins, and through it the hepatic artery, vena portæ, and hepatic plexus of nerves enter the liver, and the hepatic ducts and many of the lymph vessels leave. To the anterior and posterior margins of the fissure are attached the layers of peritoneum which constitute part of the lesser omentum.

The various structures found in the porta hepatis are arranged in the following way. The vena portæ lies posteriorly, and divides, in the fissure, into right and left branches, which run to right and left. The neck of the gall-bladder, with the cystic duct coming from it, lies at the right extremity of the fissure, and there the cystic duct bends downwards between the layers of the hepato-duodenal ligament.

The right and left bile ducts lie at their respective ends of the porta hepatis, converge towards each other at the right extremity, and lie anterior to the corresponding branches of the hepatic artery, and to the right side of the main vessel at their junction in the hepato-duodenal ligament. The nerves mainly invest the arteries, and the lymph vessels lie in the connective tissue which invests all these structures.

Two or three lymph glands are occasionally found in the porta hepatis, especially at the right end, near the neck of the gall-bladder, and when enlarged, they may press upon the ducts, and interfere with the passage of the bile.

The intervals between the vessels and other structures are filled in by loose connective tissue, which is continued inwards with the vessels as the fibrous capsule of Glisson.

When the porta hepatis is opened up, it is found to extend on the left as far as to the fossa venæ umbilicalis.

(2) **Fossa Venæ Umbilicalis** (O.T. **Umbilical Fissure**).—The fossa of the umbilical vein is a deep crevice-like fissure, of the inferior surface, directed sagittally, parallel to the gall-bladder, but about 1 to 1½ inches to its left side. It intersects the margo anterior, and passes thence backwards to the left extremity of the porta hepatis. Within this fissure lies a rounded cord-like structure, the

ligamentum teres hepatis, the remains of the left umbilical vein of the fœtus. The fissure is often crossed by a bridge of liver tissue, the *pons hepatis*, which may even extend for the whole length of the fissure, and so conceal the round ligament from view.

(3) **Fossa Ductus Venosi.**—At the dorsal end of the fossa venæ umbilicalis the ligamentum teres is attached to the left branch of the portal vein. Beyond that point it is continued backwards as a fine fibrous band, the **ligamentum venosum (Arantii)**, which joins the vena cava inferior. This fibrous cord is the remains of the ductus venosus, and lies in a groove on the posterior aspect of the liver, called the **fossa of the ductus venosus.**

The umbilical vein and the ductus venosus in the fœtus convey the blood back from the placenta to the inferior vena cava.

The umbilical fossa and the fossa of the ductus venosus together form a continuous fossa on the inferior and posterior surfaces which divides them into a right and left lobe. This fossa is known as the **fossa sagittalis sinistra**, in contrast to the porta hepatis, and to the **fossa sagittalis dextra**, lying to the right, which is made up of the following two fossæ:

(4) **Fossa Vesicæ Felleæ.**—The **fossa of the gall-bladder** is a slight depression which begins (often as a notch) at or near the margo anterior of the liver, and passes backwards and to the left, as far as the porta hepatis (Fig. 918). In it lies the gall-bladder, united to it by areolar tissue.

(5) **Fossa Venæ Cavæ.**—The **fossa of the vena cava** is a deep groove, on the posterior surface, on the right side of the caudate lobe, in which the superior part of the vena cava inferior is embedded, immediately before it pierces the diaphragm.

The depressions for the gall-bladder and the vena cava are rightly called fossæ. In hardened specimens it will be seen that the fossa for the umbilical vein, the porta hepatis, and the fossa for the ductus venosus are really fissures.

Taken together, the four fossæ and the porta hepatis are arranged somewhat in the form of the letter A (Fig. 918); the two lower divisions of the diverging limbs being formed by the fossa venæ umbilicalis and the fossa vesicæ felleæ respectively, and the cross-piece by the porta hepatis—all of which are placed on the inferior surface. The two upper divisions of the limbs are represented by the fossae of the ductus venosus and of the vena cava, which meet above and are both placed on the posterior surface. The fossa of the vena cava, represented by the right upper division of the A, does not join the cross-piece (the porta hepatis), but is separated from it below by a narrow ridge of liver substance—the **processus caudatus** (Fig. 918).

To the right of the A is the **lobus hepatis dexter**, to its left the **lobus hepatis sinister.**

The interior of the A is filled by the **lobus quadratus** anteriorly and the **lobus caudatus [Spigeli]** posteriorly, both of which are described as parts of the right lobe, while the processus caudatus cuts across the stem of the A behind the cross-piece, and connects the lobus caudatus (Spigeli) to the lobus hepatis dexter.

Lobi Hepatis (Lobes of the Liver).—As has been pointed out, the attachment of the ligamentum falciforme to the superior surface of the liver divides that aspect of the organ into right and left lobes. Similarly, upon the inferior surface, the fossa sagittalis sinistra is taken as dividing this aspect into right and left lobes.

Lobus Hepatis Sinister.—The **left lobe** is much smaller and flatter than the right, and forms only about one-fifth of the whole mass.

The inferior surface of the *left lobe* is directed downwards and posteriorly, and is in contact with the superior surface of the stomach; and with the lesser curvature with its attached lesser omentum. The part which rests upon the anterior surface of the stomach is rendered concave by the pressure of that organ (Fig. 918), and is known as the **impressio gastrica**; whilst the portion to the right of this, being free from the pressure of the stomach, projects backwards over the lesser curvature against the lesser omentum in the form of a smooth rounded prominence, known as the **tuber omentale.**

Lobus Hepatis Dexter.—The inferior and posterior surfaces of the **right lobe** are

intersected by the porta hepatis and the right sagittal fossa, and by them it is subdivided into other parts, which also are called lobes. These are the **lobus caudatus [Spigeli]** with the **processus caudatus**, the **lobus quadratus**, and the right lobe proper.

(1) **The Lobus Quadratus.**—This is a quadrilateral area extending from the margo anterior in front to the porta hepatis behind. On the right, it extends as far as the fossa for the gall-bladder, and on the left to the fossa for the umbilical vein. The surface is flattened or concave, and is mainly in contact with the pyloric part of the stomach and the duodenum.

The **quadrate lobe** is of an oblong shape, the antero-posterior diameter being the greatest. Its surface is generally concave, and is related to the pylorus and the adjacent parts of the stomach

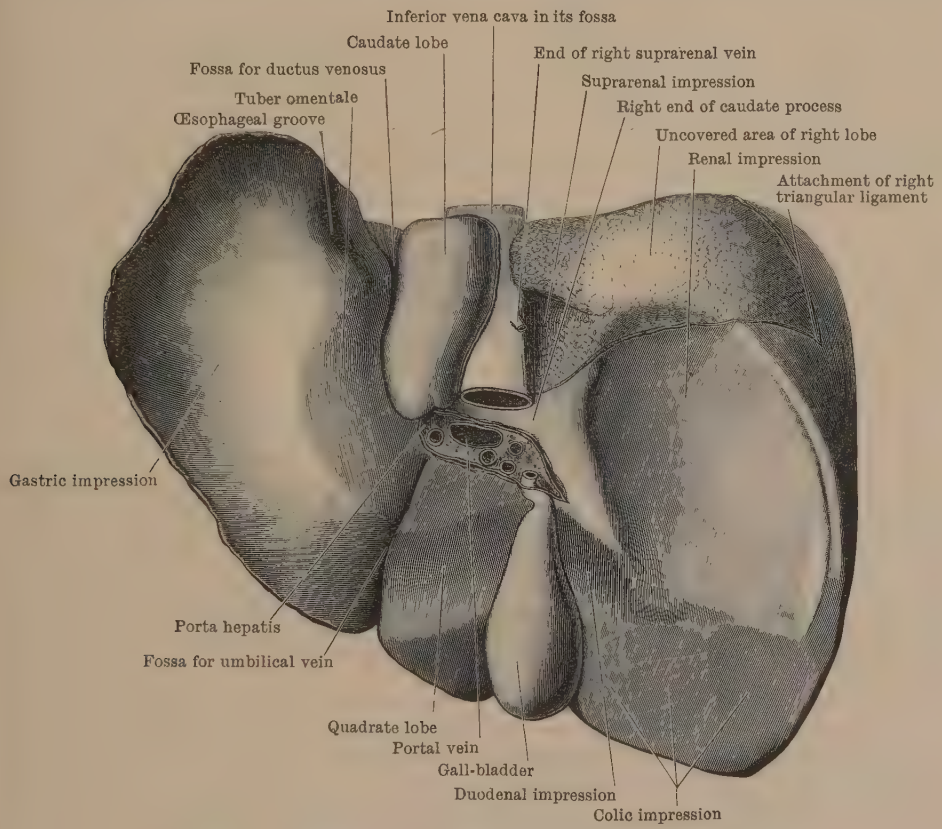

Fig. 918.—Inferior and Posterior Surfaces of the Liver.

and duodenum, when the former is distended. When the stomach is empty, however, the pylorus usually lies beneath the right portion of the left lobe, and the superior part of the duodenum lies beneath the quadrate lobe, the transverse colon also coming in contact with it anteriorly (Fig. 899).

(2) **The Lobus Caudatus [Spigeli].**—This is a prominent rather quadrilateral area on the posterior surface, between the fossa for the inferior vena cava on its right, and the fossa for the ductus venosus on its left side.

Its superior limit is formed by the terminal part of the ductus venosus, as it bends to the right to join the vena cava inferior, while, inferiorly, it is free and forms the posterior boundary of the porta hepatis.

This extremity is often grooved by a notch (in which the cœliac artery lies, particularly in the fœtus), which marks off a larger and more prominent left part, the **processus papillaris**, projecting downwards behind the porta hepatis, and a smaller right part, the **processus caudatus**, which connects it (Fig. 918) with the inferior surface of the right lobe.

The posterior surface of the caudate lobe is free; it is placed vertically, and looks backwards and slightly to the left. The lobe has also another surface, which is hidden when in the body and in the hardened liver by the folding of the left lobe across it. By this folding there is formed the deep fossa for the ductus venosus.

(3) The **processus caudatus** (O.T. **caudate lobe**) is merely a narrow bridge of liver tissue which connects the caudate lobe with the right lobe proper. It is limited anteriorly by the porta hepatis, and posteriorly by the fossa for the inferior vena cava. It forms the superior boundary for the epiploic foramen, and so a finger placed in the foramen rests against the caudate process, and has a vein in front and behind, separated by a layer of peritoneum.

(4) **The right lobe proper**, lying to the right of the gall-bladder, is entirely occupied by three impressions, produced by the underlying viscera—namely: (1) The **impressio colica** lies in front. It is formed by the right flexure of the colon and the beginning of the transverse colon. (2) Behind this is the **impressio renalis**, larger than the preceding, which is produced by the superior half or two-thirds of the right kidney. The superior end of the renal impression is frequently devoid of peritoneum (Fig. 918), that is to say, the "uncovered area" of the right lobe extends down over the impression for a little way. This impression is very deep, and accommodates nearly the whole thickness of the kidney. (3) To the medial side of the renal impression, and near the neck of the gall-bladder, is placed the narrow **impressio duodenalis**, which lies in contact with the descending part of the duodenum down to the point at which it is crossed by the colon.

Facies Posterior (Posterior Surface).—This surface is directed backwards, and lies largely in contact with the diaphragm, which here forms the posterior abdominal wall. It is very irregular in shape, and presents the following parts: (1) The "uncovered area" of the right lobe; (2) the supra-renal impression; (3) the fossa for the vena cava; (4) the caudate lobe, separated by the fossa for the ductus venosus from (5) the œsophageal groove, which belongs to the left lobe.

(1) The "**uncovered area**" of the right lobe (Fig. 917) is a considerable portion of the posterior surface of the right lobe—varying from $1\frac{1}{2}$ to 3 inches (3·7 to 7·5 cm.) in width, and from 3 to 5 inches (7·5 to 12·5 cm.) in transverse measurement—which is devoid of peritoneum. Over this uncovered portion, which looks more medially than backwards, the liver and diaphragm are in direct contact, and are united by areolar tissue; here too is established a communication by small veins between the portal circulation of the liver and the systemic circulation of the diaphragm.

(2) **Impressio Suprarenalis.**—On the "uncovered area," immediately to the right of the vena cava, is a triangular impression (Fig. 917), produced by a portion of the right suprarenal gland, which projects upwards from the superior extremity of the right kidney, between the diaphragm and liver.

(3) **Fossa Venæ Cavæ.**—At the left extremity of the "uncovered area" the inferior vena cava lies vertically, embedded in a fossa of the liver substance, between the caudate lobe on the left and the adjacent part of the uncovered area on the right, both of which project over the sides of the vein, almost hiding it from view (Fig. 918); sometimes they actually meet and form a **pons hepatis** across the back of the vein.

(4) **Lobus Caudatus [Spigeli].**—This has already been described—*see above.* The superior recess of the omental bursa separates the posterior surface of the caudate lobe from the diaphragm, which latter, in turn, separates it from the thoracic part of the descending aorta just before that vessel enters the abdomen.

(5) The **Impressio Œsophagea**, or œsophageal groove, is situated on the posterior surface of the left lobe, to the left of the superior end of the caudate lobe, but is separated from it by the fossa for the ductus venosus. The groove leads down into the gastric impression on the inferior surface of the left lobe (Fig. 918).

Surface Markings of the Liver.—The limits even of the normal liver are very variable, but, taking the average condition in the male, they may be marked out on the anterior surface of the body by the following method: Three points are determined—(*a*) half an inch (12·5 mm.) below the right nipple; (*b*) half an inch

(12·5 mm.) below the right margin of the thorax (or below the tip of the tenth rib); and (*c*) one inch (25 mm.) below the left nipple. If these points are joined by three lines, slightly concave towards the liver, they will give the outline of the organ with sufficient accuracy for all ordinary purposes.

To state the matter somewhat more in detail: If the two "nipple points" (*a*) and (*c*) be joined by a line, slightly convex upwards on each side, but a little depressed at the centre corresponding to the position of the heart, and crossing the inferior end of the sternum about the level of the seventh cartilage, it will mark the superior limit. A line, convex upwards, from the right nipple point (*a*) to the subcostal point (*b*) will indicate the right limit, while the inferior limit is marked by a line, convex downwards, drawn from the subcostal point (*b*) to the left nipple point (*c*), and passing through a point half-way between the umbilicus and the inferior end of the body of the sternum, in the median line.

The line indicating the superior limit of the liver is elevated on each side, corresponding to the cupolæ of the diaphragm, and depressed in the centre beneath the heart. On the right side where highest, namely, about one inch (25 mm.), medial to the mammary line, it reaches during expiration to the superior border of the fifth rib; on the left side it is one-half to three-quarters of an inch (12 to 18 mm.) lower; and it crosses behind the sternum at the level of the sixth sterno-costal junction—or sometimes lower. It must be remembered, however, that whilst the liver reaches up to the levels just given, it does so only at the highest part of its convex parietal surface, and is separated from the ribs all round by the thin lower margin of the lung (which extends down between the chest wall and diaphragm to the sixth rib in front, to the eighth in the mid-lateral line, and to the level of the tip of the spine of the tenth thoracic vertebra behind), so that, in percussing over the liver, its dulness is obscured by the resonance of the lungs above these points.

From the back, the superior margin of the liver rises as high as to the *superior* margin of the eighth rib or to the inferior margin of the scapula on the right side. On the left, it rises to the *inferior* margin of the eighth rib, and terminates about an inch medial to the inferior angle of the scapula.

The inferior margin slopes upwards along the eleventh rib of the right side, along a line leading to the superior part of the tenth thoracic vertebra. On the right side the liver extends vertically in the mid-axillary line from the sixth to the eleventh ribs.

Variations in Size, Form, and Position.—Few organs will be found to vary more in **size** in different bodies than the liver; these variations, however, are very frequently to be looked upon as pathological. But even the normal, healthy liver may vary in weight from 48 to 58 ounces in the adult male, and from 40 to 50 ounces in the female.

Variations in form and **position** doubtlessly take place physiologically, as a result of the conditions of fulness or emptiness of the adjacent viscera; for, though the liver, like the other solid abdominal organs, has an intrinsic shape of its own, this is capable of modification within certain limits by the varying pressure of the surrounding parts. Thus, distension of the stomach, or of a portion of the transverse colon lying in the stomach chamber, may push the liver over to the right, so that it may hardly reach the median plane, and at the same time it increases its vertical depth. On the other hand, a distended state of the small intestines, with a contracted stomach and colon, may have the opposite effect, flattening it from below upwards and enlarging it in the transverse direction.

Variations in form and position *due to malformations* of the thoracic framework, either congenital or acquired, were very common, particularly in females as a result of tight-lacing, which presses the lower ribs inwards. Sometimes in these cases the constriction of the waist lies chiefly below the liver. The organ is then forced up against the diaphragm, filling its whole vault, and extending across to the left abdominal wall, where its left margin may lie in the interval between the diaphragm and the spleen. But more commonly it would seem that the liver is caught by the constriction: its upper part is then closely pressed into the vault of the diaphragm, which, owing to the narrowing of the thorax, is unable to accommodate the whole organ, so that its inferior part is crushed down for a considerable distance into the umbilical zone of the abdomen (Fig. 896, p. 1161), particularly on the right side. Often, too, a wide, tongue-like process (the so-called "Reidel's lobe") descends from the inferior margin, lateral to the gall-bladder. This process, which when very large may reach to the iliac crest, is sometimes found in men, although more common in women, and is liable to be mistaken for a tumour. A somewhat similar process occasionally descends from the left lobe.

Again, in apparently healthy bodies the liver may extend up on the right side almost to the fourth rib; whilst in other cases it may be as low as the sixth rib, or even lower. Nor is it rare—particularly in females—to find the anterior border projecting two or three inches (5·0 to 7·5 cm.) below the margin of the thorax on the right side (Fig. 896, p. 1161).

Reference should be made here to certain grooves often seen on the liver. Some of these are found running obliquely low down at the right side where the liver is in contact with the ribs; they are particularly common in females, and are due to the pressure of the ribs resulting from tight-lacing. Grooves of a different kind are found at the superior part of the parietal surface; where the liver is in contact with the diaphragm; these usually run radially, that is, in the direction of the muscular fibres of the diaphragm, and are apparently produced by a wrinkling, or irregular contraction, of the diaphragm. At least, ridges of the diaphragm are found lying in the grooves, and these ridges or wrinkles would seem to be responsible for the production of the grooves.

Finally, the liver may present certain **congenital irregularities** in the direction of additional fossæ and lobes, which reproduce the conditions found in the higher apes, and are very commonly present in the fœtus (Thomson). Or the liver may be divided up into a large number of distinct lobes, as in most other animals.

Changes in position have been already referred to in connexion with variations in form; there need only be added here that the liver ascends and descends at every expiration and inspiration respectively, and that it also descends, but very slightly, in changing from the reclining to the erect posture. Occasionally, without any evident cause, the liver and diaphragm are found to occupy a higher or lower position than usual.

Fixation of the Liver.—At first sight it is not easy to understand the means by which the liver maintains its position in the abdomen (and the same remark applies, perhaps, to other solid abdominal organs). The falciform ligament gives it no support, as it is quite lax when in the body. Nor can it be said that its vessels, except perhaps the hepatic veins, assist. However, on considering the conditions under which the viscera are placed in the abdominal cavity the problem becomes less difficult.

The abdomen is a closed cavity, with a firm framework to its superior part, a tightly stretched diaphragm for its roof, and muscular walls all round. Into the concavity of this roof the parietal surface of the liver is fitted with perfect accuracy, so that the two are in absolute contact, and cannot be separated without producing a vacuum, unless some other structure is in a position to fill the space. But there is hardly any other viscus movable enough to pass up over the front of the liver into the vault of the diaphragm, so that atmospheric pressure alone is probably sufficient to retain the organ *in situ*, as in the case of the shoulder joint. In addition, the abdominal muscles are always in a condition of tonic contraction or "tone," which gives rise to an intra-abdominal pressure. This is effective in all directions, and consequently there is a considerable pressure on all the abdominal walls. The liver, being in absolute contact with the roof, may be considered a part of this wall, and it is consequently affected by this pressure which helps to sustain it. Add to this, the support which the organ receives from the intestines, the stomach, and the pancreas; from the coronary and triangular ligaments; from the connexion of the back of the right lobe by areolar tissue to the diaphragm; and, finally, from the inferior vena cava embedded in the liver and sending its hepatic veins forwards to all parts of the organ, just before the vein itself is firmly attached to the margins of the caval orifice in the central tendon of the diaphragm, and we will probably find sufficient cause for the maintenance of the organ in its position in the abdominal cavity.

Relation to Peritoneum.—The relation of the liver to the peritoneum is somewhat complex in its details. The greater part of the liver is covered with peritoneum, forming the tunica serosa, but over an area of some size upon its superior and posterior aspects it is directly in contact with the diaphragm, and round the margins of this area the peritoneum passes from liver to diaphragm. This is known as the bare area, and the peritoneum around this area forms the **ligamentum coronarium (coronary ligament).** Further, the liver is attached to the anterior portion of the diaphragm, and to the abdominal wall as low as to the umbilicus by a fold of peritoneum which is known as the **ligamentum falciforme.** This fold runs forwards from and is continuous with the folds of peritoneum which limit the bare area, and the whole forms a sort of mesentery or meso-hepaticum.

The peritoneum is also reflected off from the margins of the porta hepatis and from the fossa for the ductus venosus, and passes thence to the lesser curvature of the stomach and the first part of the duodenum, forming the omentum minus. The liver may, in fact, be regarded as lying inside a peritoneal fold which stretches from the lesser curvature of the stomach below to the diaphragm and anterior abdominal wall above. This fold is embryologically the ventral mesentery of the stomach, or ventral meso-gastrium, and its original simple character has become complicated by the growth of the liver within it and by the rotation which the stomach undergoes to the right side.

The various ligaments of the liver are as follows:—

(1) **Ligamentum Falciforme Hepatis.**—The **falciform ligament of the liver** is a crescentic fold of peritoneum, which is attached by its convex border to the inferior surface of the diaphragm, and to the anterior abdominal wall (an inch or more to the right of the median plane) to within a short distance (1 to 2 inches, 2·5 to 5 cm.) of the umbilicus. Its opposite border is attached to the superior and anterior aspects of the liver; below this level it presents a free rounded edge, stretching from near the umbilicus to the umbilical notch of the liver, and it contains within its layers a stout fibrous cord called the round ligament.

Near the posterior part of the superior surface of the liver the two layers of which the falciform ligament is composed separate, and enclose a triangular area on the posterior surface, in front of

the superior end of the vena cava, uncovered by peritoneum. Traced backwards, the right layer passes into the superior layer of the coronary ligament, the left into that of the left triangular ligament (Fig. 916).

(2) **Ligamentum Coronarium Hepatis.**—The **coronary ligament** consists of the layers of peritoneum which are reflected from the liver to the diaphragm at the margins of the uncovered area of the right lobe. The name of **right triangular ligament** has been given to its pointed right extremity (Fig. 919).

The coronary ligament consists of a superior and an inferior layer. The superior is formed by the prolongation to the right of the right layer of the falciform ligament. The inferior layer is formed by the continuation of the inferior layer of the right triangular ligament to the left side, and by the reflexion from the margin of the caudate lobe by the side of the inferior vena cava (see Fig. 919).

(3) **Ligamentum Triangulare Dextrum.**—The **right triangular ligament** (O.T. **right**

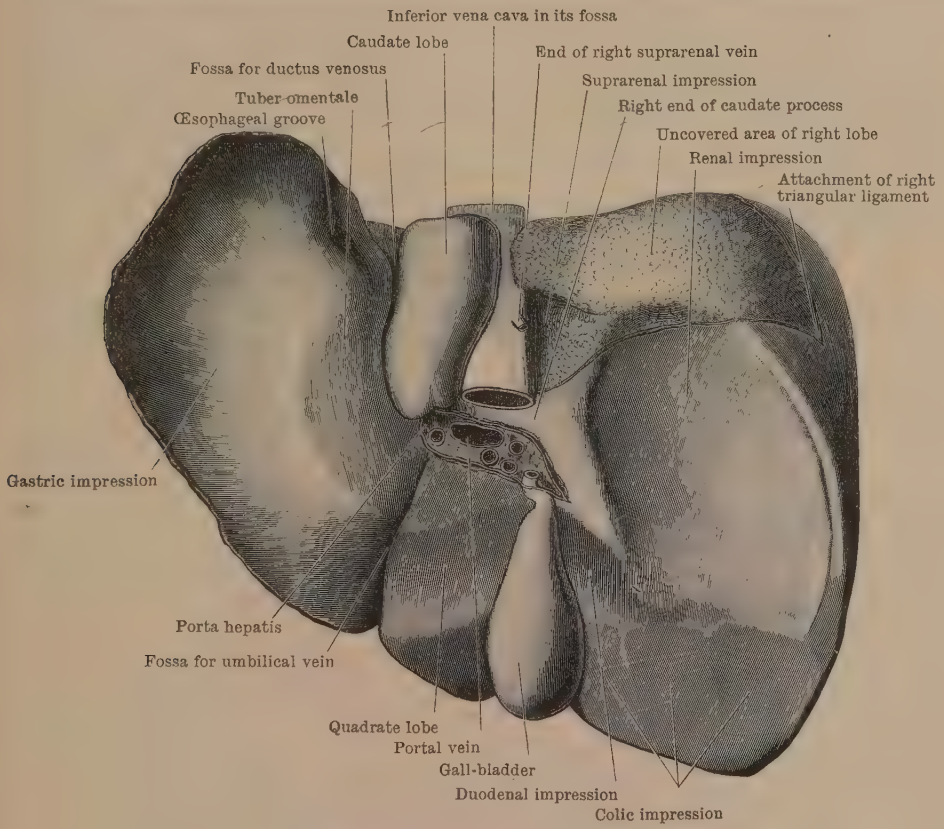

Fig. 919.—Inferior and Posterior Surface of the Liver.

lateral ligament) is merely the pointed right extremity of the coronary ligament, where the superior and inferior layers become continuous with one another.

(4) **Ligamentum Triangulare Sinistrum.**—The **left triangular ligament** (O.T. **left lateral ligament**) is a considerable triangular fold, continuous with the left layer of the falciform ligament, which is attached by one border to the superior surface of the left lobe near its posterior border, and by the other to the diaphragm, for a distance of several inches as a rule.

Its attachment to the diaphragm lies nearly altogether to the left of the œsophageal orifice, and about $\frac{3}{4}$ inch (18 mm.) anterior to the plane of this opening.

Two other structures, termed ligaments, are not peritoneal folds, but obliterated blood-vessels, namely the ligamentum teres hepatis or round ligament and the ligamentum venosum (Arantii).

(5) **Ligamentum Teres Hepatis.**—The **round ligament of the liver** is a stout fibrous band which passes from the umbilicus, backwards and upwards, within the free margin of the falciform ligament, to the umbilical notch of the liver, and thence upwards and

backwards in the umbilical fossa, to join the left branch of the portal vein. It is the remains of the left umbilical vein, which, before birth, carries the arterial blood from the placenta to the body of the fœtus (Fig. 916).

(6) **Ligamentum Venosum [Arantii].**—The **venous ligament** (O.T. **obliterated ductus venosus**) is a slender fibrous cord, which passes from the left branch of the portal vein, nearly opposite the attachment of the round ligament, upwards in the fossa bearing its name, to be connected with the inferior vena cava as it leaves the liver. In the fœtus this structure is a considerable vessel, which conveys some of the blood brought to the porta hepatis by the left umbilical vein directly backwards to the vena cava. At the time of birth the ductus venosus and umbilical vein cease to carry blood, their cavities become obliterated, and they are converted into fibrous cords.

(7) **Omentum Minus.**—The **lesser omentum** is a fold of peritoneum which extends from the liver to the lesser curvature of the stomach and to the duodenum (see p. 1155).

The "bare area" of the liver is triangular in shape, and measures about 3 inches in its greatest vertical extent, and some 5 inches transversely. It is in contact with the diaphragm, a portion of the right suprarenal gland, and the inferior vena cava. It is bounded above and below by the superior and inferior folds of the coronary ligament, and on the left by the attachment of peritoneum to the margin of the caudate lobe. It is prolonged upwards for a short distance on the superior surface of the liver, in front of the inferior vena cava, between the layers of the falciform ligament as they diverge from one another.

Structure of the Liver.

The liver is invested by an outer **tunica serosa** described in connexion with the peritoneum. Within this is a thin **capsula fibrosa [Glissoni]** of delicate fibrous tissue, which is most evident

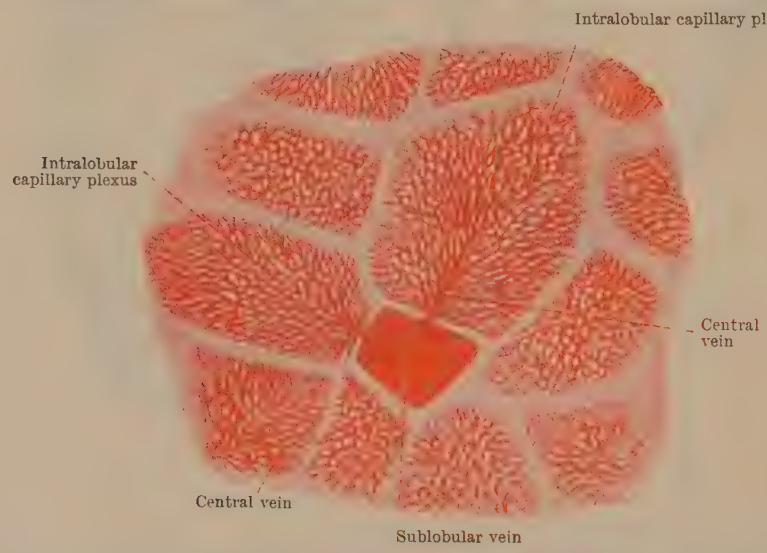

Fig. 920.—Liver of a Pig injected from the Hepatic Vein by T. A. Carter. (From a specimen presented to the Anatomical Department of Edinburgh University by Sir William Turner.)

where the serous coat is absent. In the neighbourhood of the porta hepatis it is particularly abundant, and here it surrounds the vessels entering the porta, and accompanies them through the portal canals in the liver substance. This coat is continuous with the fine areolar tissue which pervades the liver, surrounding its lobules and holding them together.

The liver substance proper is made up of an enormous number of small **lobules** $\frac{1}{25}$th to $\frac{1}{12}$th inch (1 to 2 mm.) in diameter, closely packed, and held together by a small amount of connective tissue. In man the lobules are not completely separated from one another all round their circumference, but coalesce in places; the reverse is the case in certain animals such as the camel and the pig. Each lobule is composed of a large number of columns of liver cells, radiating from the centre to the periphery.

Between the columns—which interlace freely—is a sinusoidal vascular network through which blood passes from marginal veins—interlobular—to a central vein.

The endothelial wall of this network is incomplete, so that the liver cells are in many places in contact with the blood, and in other parts the endothelial cells are modified into stellate cells

which are believed to have a special phagocytic property ("star cells" of Kupfer). The columns may be regarded as being composed of two layers of cells, between which is a minute channel, the intralobular duct, passing from the centre to the periphery of the lobule.

Vessels of the Liver.—Blood is conveyed to the liver by the hepatic artery and the portal vein, which enter the liver at the porta hepatis, and break up into branches and finally into capillaries. The blood which has so entered is conveyed from the liver by the hepatic veins to the vena cava inferior.

The circulation within the liver is, therefore arranged differently from that of other glands, and in order to understand properly the structure of the liver, it is necessary to give some account of the relations which it presents to the blood-vessels which pass to and from it.

The **vena portæ** and the **arteria hepatica propria** pass up to the liver between the two layers of the hepato-duodenal ligament, anterior to the foramen epiploicum. Here they are accompanied by the bile-duct, which lies to the right, whilst the artery is placed to the left, and the portal vein posterior to both. In this order they enter the porta hepatis, and there become rearranged, so that the vein lies behind, the artery in the middle, and the duct in front. Each breaks up into two chief branches—a right and a left—and several smaller ones, which enter the liver substance, surrounded by a prolongation of the connective tissue coat of the liver (O.T. Glisson's capsule). Within the organ the three vessels run and divide together, so that every branch of the portal vein is accompanied by a corresponding (but much smaller) branch of the hepatic artery and of the hepatic duct; and the three, surrounded by a prolongation of the fibrous capsule, and accompanied by branches of the hepatic nerves and lymph vessels, run in special tunnels of the liver substance, which are known as **portal canals** (Fig. 921, B).

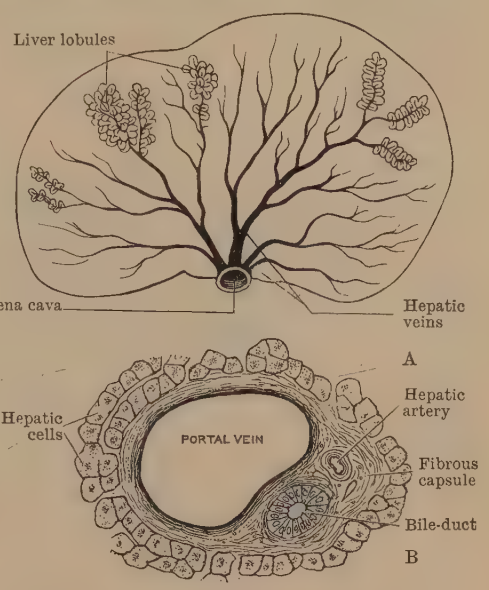

FIG. 921.—DIAGRAMS ILLUSTRATING THE STRUCTURE OF THE LIVER.

A, Arrangement of liver lobules around the sublobular branches of the hepatic vein; B, Section of a portal canal, showing its contained branches of the portal vein, hepatic artery, and bile-duct, surrounded by a prolongation of Glisson's fibrous capsule.

The hepatic artery has but a small part to play in the hepatic circulation within the liver and it supplies minute branches, known as the vaginal and capsular branches, to the fibrous tissue of the portal canals and of the surface of the liver. The terminal branches of the artery end in the capillaries from the portal vein which go to the liver lobules.

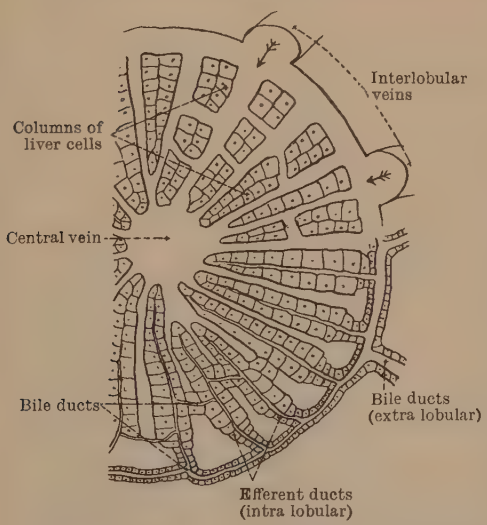

FIG. 922.—DIAGRAM TO ILLUSTRATE THE STRUCTURE OF A LIVER LOBULE.

The portal vein within the liver divides, like an artery, into numerous branches, which eventually form an elaborate meshwork, whose vessels anastomose freely with one another, around the periphery of the liver lobules, and are known as *interlobular vessels*. From this meshwork small capillary-like channels pass into the interior of each lobule between columns of liver cells, towards a channel in the centre of the lobule, called the *central vein*. From the central veins the blood is carried into larger channels or *sublobular veins*, which pass to the hepatic veins.

The hepatic veins gradually unite with one another, and run towards the inferior vena cava. Their mode of termination is variable, but presents the following general arrangement:—The left lobe is drained by a vessel which joins the superior part of the inferior vena cava. The right lobe is drained by one or two vessels which join the superior part of the inferior vena cava, and by a series of small vessels, 4 to 12 in number, which pass from the inferior portion of the right lobe to the inferior vena cava. The caudate lobe and central portion of the liver are drained by vessels which mostly pass to the inferior part of the

inferior vena cava. The hepatic veins and their branches are not accompanied by branches of the bile-ducts, and are surrounded by a very small amount of connective tissue.

The **lymph vessels** of the liver are arranged in a superficial and a deep set:—1. The **superficial set** lies beneath the peritoneum on both (*a*) the visceral and (*b*) the parietal surfaces of the organ. (*a*) The vessels from the *visceral surface* pass chiefly to the hepatic glands, which lie between the layers of the lesser omentum; but some of them, from the posterior surface on the right lobe, join the lumbar glands, and others, from the posterior surface on the left lobe, go to the cœliac glands. (*b*) The vessels from the superior surface pass in various directions. Those from the adjacent parts of the right and left lobes pass up in the falciform ligament, and pierce the diaphragm to reach the anterior mediastinal glands, and end finally in the right lymphatic duct. Those from the anterior part of this surface pass down to the inferior aspect, and join the hepatic glands in the lesser omentum. The lymph vessels from the back of the right lobe pierce the diaphragm between the layers of the coronary ligament, and join some glands in the thorax around the upper end of the inferior cava; others run in the right triangular ligament, and either pierce the diaphragm and end in the anterior mediastinal glands, or, turning down, join the cœliac group.

2. The **deep lymph vessels** accompany either (*a*) the portal or (*b*) the hepatic veins. (*a*) The former set pass out through the porta hepatis and join the hepatic glands, the efferent vessels of which join the cœliac glands. (*b*) Those which accompany the hepatic veins pierce the diaphragm with the vena cava, and having formed connexions with the group of glands at its superior end, within the thorax, turn down and join the beginning of the thoracic duct.

The **nerves**, which are chiefly of the non-medullated variety, are derived from the left vagus and the cœliac plexus of the sympathetic. The branches of the former pass from the front of the stomach up between the layers of the lesser omentum to the liver and supply the gall-bladder and bile-ducts. Those of the latter pass from the cœliac plexus along the hepatic artery—forming the hepatic plexus—to the porta hepatis, where they enter the liver with the blood-vessels. They are distributed chiefly to the walls of the vessels.

THE GALL-BLADDER AND BILE-PASSAGES.

The excretory ducts of the liver begin within the hepatic cells as minute channels. Thence they run between the hepatic cells (Fig. 922), and are known as the **ductus biliferi.**

Outside the lobules these join (Fig. 922) the **ductus interlobulares**, which, by uniting, form larger and larger ducts, and finally end in two, or more, chief branches, a larger from the right, and a smaller from the left lobe, which unite immediately after leaving the liver to form the **ductus hepaticus.**

As a rule, five or six ducts leave the liver at the porta hepatis; they generally unite into right and left main ducts; sometimes they all converge towards, and unite at the beginning of the hepatic duct. The ducts from the caudate lobes and process join the left branch of the main duct.

Ductus Hepaticus.—The **hepatic duct** is formed within the porta hepatis by the union of right and left chief ducts (Fig. 923), passes downwards, and, just beyond the porta hepatis, is joined by the **cystic duct** (Fig. 923) to form the **ductus choledochus** (**bile-duct**, O.T. **common bile-duct**). In length the hepatic duct usually measures about 1 to 1¼ inch (25 to 31 mm.), and in breadth, when flattened out, nearly ¼ inch (6 mm.), or about as much as a goose quill. It lies, practically altogether, within the porta hepatis.

Vesica Fellea (Gall-bladder).—The **gall-bladder**, with the cystic duct, may be looked upon as a diverticulum of the bile-duct, enlarged at its extremity to form a reservoir for the bile. It is pear-shaped, and lies obliquely on the inferior surface of the liver (Fig. 923). The wide end, or **fundus**, usually reaches the anterior border of the liver and comes in contact with the anterior abdominal wall (Fig. 928). The **corpus (body)** runs backwards, upwards, and to the left, lying in the fossa for the gall-bladder, and near the porta hepatis passes rather abruptly into the narrow neck. The **collum (neck)** is curved medially towards the porta hepatis, in the form of the italic letter *s*, and when distended it presents on its surface a spiral constriction which is continued into the beginning of the cystic duct, and is due to a series of crescentic folds placed somewhat spirally round the interior of its cavity, forming the **valvula spiralis (Heister).** Having arrived near the porta hepatis, much reduced in size, it passes into the cystic duct.

As a rule the gall-bladder is covered by the peritoneum of the inferior surface of the liver, except on its antero-superior aspect, which is united to the fossa for the gall-bladder by areolar tissue. Sometimes, but rarely, the gall-bladder is suspended from the liver by a short peritoneal ligament. *Above*, the gall-bladder lies

against the liver; and *below*, it rests on the transverse colon in front, and behind, near its neck, on the duodenum.

In some cases the fundus of the gall-bladder does not reach the anterior border of the liver or the abdominal wall. In others it may be moved considerably to the right of the vertical lateral plane — possibly as a result of distension of the stomach and colon — or as a result of tight-lacing it may lie to the left, near the median plane and far below the ribs (Fig. 896, p. 1161).

Its total absence, as well as the presence of two distinct gall-bladders, and several other irregularities in form, have been recorded.

Its *size* is usually about 3 inches (75 mm.) in length, and 1 to 1¼ inches (25 to 31 mm.) in diameter. Its capacity varies between 1 and 1½ fluid ounces.

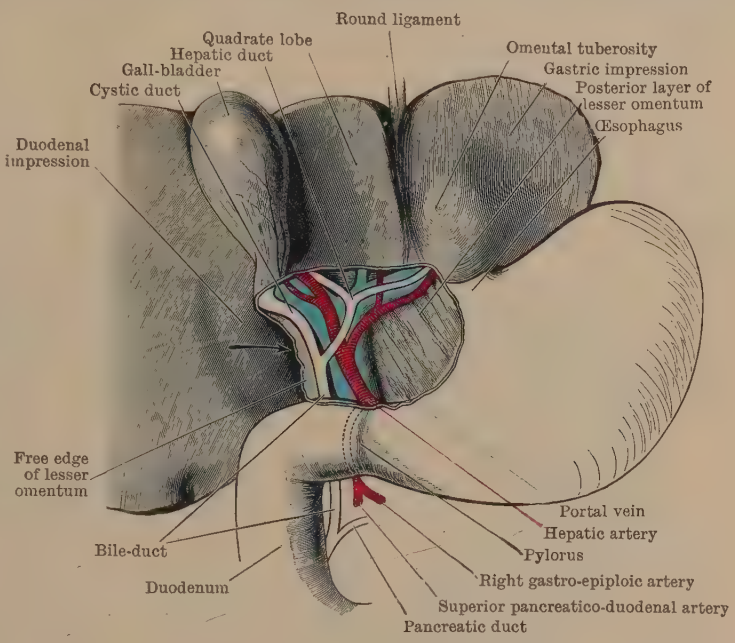

Fig. 923.—Structures between the Layers of the Lesser Omentum.

Structure of Gall-bladder.—The wall of the gall-bladder is composed of an outer coat of peritoneum, the *tunica serosa*, usually incomplete; a middle coat of unstriped muscle intermixed with fibrous tissue, the *tunica muscularis*; and an inner coat of mucous membrane, the *tunica mucosa*, which is covered with columnar epithelium, and is raised into a number of small ridges, the *plicæ tunicæ mucosæ*, which confer on it a reticulated appearance. The mucous membrane is always deeply stained with bile when the gall-bladder is opened after death.

The **cystic artery** which supplies it with blood arises from the hepatic artery itself, or its right division, and divides into two branches, which run on the sides of the gall-bladder. The **veins** join the vena portæ, and the **nerves** come from the sympathetic plexus on the hepatic artery.

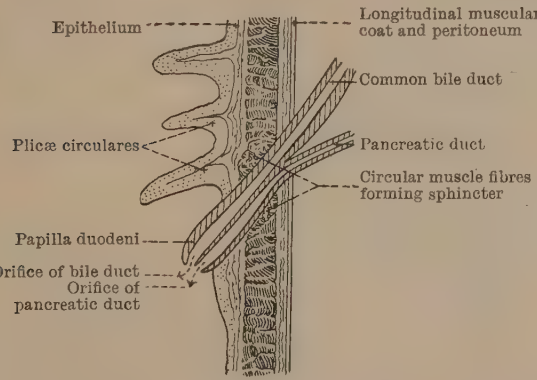

Fig. 924.—Diagrammatic Section of Wall of Duodenum through Papilla.

Ductus Cysticus.—The **cystic duct**, about half the diameter of the hepatic duct (3 mm.), but usually slightly longer (1¼ to 1½ inches: 31 to 37 mm.), begins at the neck of the gall-bladder, pursues an irregular course backwards and medially, and joins the hepatic duct at the mouth of the porta hepatis, to form the bile-duct. The spiral constriction found in the neck of the gall-bladder is continued into the beginning of this duct. Sometimes the cystic duct joins the right hepatic duct instead of the hepatic duct proper.

Ductus Choledochus.—The **bile-duct** (O.T. **common bile-duct**) begins at the mouth of the porta hepatis, where it is formed by the union of the hepatic and cystic ducts. Thence it passes downwards, anterior to the foramen epiploicum, lying

between the two layers of the lig. hepato-duodenale, with the portal vein behind and the hepatic artery to its left. It descends behind and to the left of the superior part of the duodenum (Fig. 923), and then between the pancreas and descending part of the duodenum. Finally, it meets the pancreatic duct, and the two, running together, pierce the medial wall of the descending part of the duodenum very obliquely, and open on the papilla duodenalis about $3\frac{1}{2}$ or 4 inches (8·7 to 10 cm.) beyond the pylorus (see p. 1179).

The length of the bile-duct is about 3 inches (75 mm.), and its diameter, which is very variable, is generally about $\frac{1}{4}$ inch (6 to 7 mm.).

Structure of the Excretory Ducts.—With the exception of the peritoneal coat, which is absent, the hepatic, cystic, and bile-ducts agree with the gall-bladder in general structure. The tunica mucosa contains a large number of mucus-producing glands, the **glandulæ mucosæ biliosæ.**

The bile and pancreatic ducts, in piercing the wall of the duodenum, run obliquely through its coats for about $\frac{1}{2}$ or $\frac{3}{4}$ of an inch (12 to 18 mm.), and, as a rule, do not unite until they have almost reached the opening on the duodenal papilla (Fig. 924). This orifice is very much smaller than either duct, and the short and relatively wide common cavity which precedes it is sometimes known as the "ampulla of Vater." In 20 per cent of cases the cystic and hepatic ducts open into the duodenum separately.

PANCREAS.

The **pancreas** is a long, soft, lobulated reddish or yellowish gray gland, which lies transversely on the posterior abdominal wall, its right end resting in the concavity of the duodenum (Fig. 925), and its left end touching the spleen. It secretes a clear, watery, alkaline fluid—the pancreatic juice—which is conveyed to the duodenum by the **pancreatic duct**, and which constitutes one of the chief agents in intestinal digestion, for it contains ferments which can coagulate milk, transform starch into dextrin and sugar, split fats into glycerine and fatty acids, and reduce alkaline albuminous substances to peptone.

In **shape** the pancreas, when hardened *in situ* (Fig. 927), may be compared to the letter J placed thus ⊂.

The gland is divisible into a **head (caput)** with a **processus uncinatus**, a **body (corpus)**, and a **tail (cauda)**. The **head** corresponds to the hook of the ⊂. The stem of the ⊂ represents the **body** of the gland, and the thin left extremity of the body forms the **tail**. The narrow part connecting the head and body is the **neck** (Symington).

When removed from the body without previous hardening, the pancreas loses its true form, and becomes drawn out into a slender, tongue-shaped mass, with a wider end turned towards the duodenum, and a narrow end corresponding to the tail.

Its total *length*, when fixed *in situ*, is about 5 or 6 inches (12·5 to 15 cm.); after removal, if not previously hardened, it is easily extended to a length of 8 inches (20 cm.).
Its *weight* is usually about 3 ounces (87 grammes).

Relations.—The general position and relations of the pancreas may be briefly expressed as follows:—The head (Fig. 927) lies in the concavity of the duodenum, with the vena cava inferior and abdominal aorta behind it; the body crosses to the left of the spine and lies on the left kidney and supra-renal gland; and the tail touches the inferior part of the spleen. The greater part of the organ lies behind the stomach, which must be detached from the gastro-colic ligament, and turned upwards, in order to expose it.

In describing the detailed relations, each part of the organ will require to be considered separately.

Caput Pancreatis.—The **head** of the pancreas, flattened and somewhat disc-shaped, lies in the concavity of the duodenum, extending along its second and third portions almost as far as the duodenal-jejunal flexure. *Above*, in its right half, it is continuous with the neck; whilst to the left of this it is separated from the neck by a deep notch.

incisura pancreatis, in which lie the superior mesenteric vessels (Fig. 925). Its *right* and *inferior borders* are moulded on to the side of the duodenum, which lies in a groove of the gland substance—the bile-duct being interposed as far down as the middle of the descending part of the duodenum. The *posterior surface* of the head is applied to the

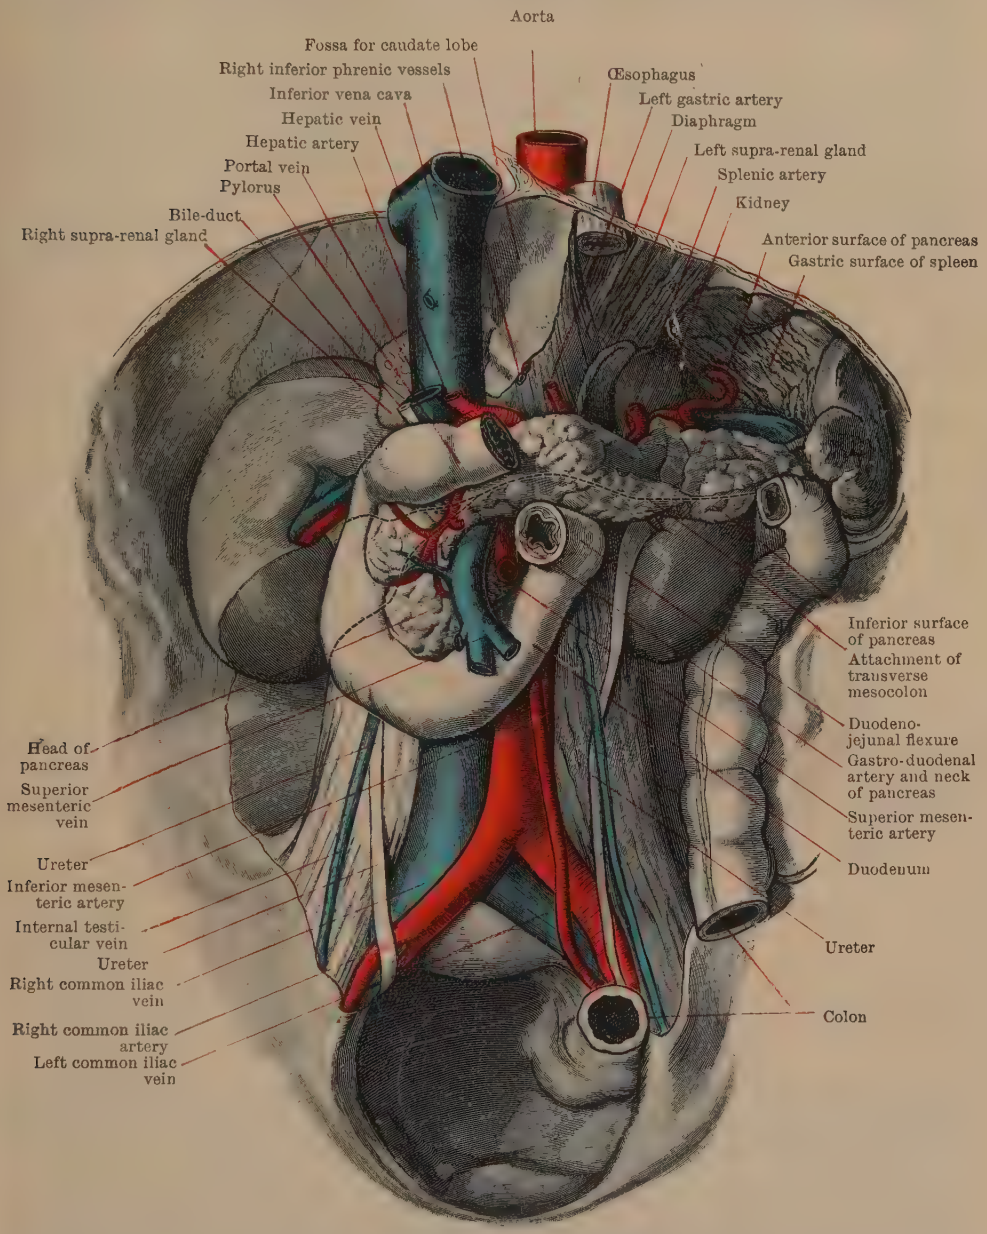

FIG. 925.—THE VISCERA AND VESSELS ON THE POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney and the fossa for the caudate lobe. When the liver was taken out, the inferior vena cava was left behind. The stomach bed is well shown. (From a body hardened by chromic acid injections.)

front of the vena cava inferior, the right renal vessels and the left renal vein, and, at its left end, of the aorta as well. Its *anterior surface* is in contact above and on the right with the beginning of the transverse colon (Fig. 912), without the interposition of the peritoneum as a rule. Below this it is clothed by peritoneum, and is covered by the small intestine.

The **superior mesenteric vessels**, after passing forward through the pancreatic notch, descend in front of that portion of the head (processus uncinatus) which runs to the left

along the third part of the duodenum. The **superior pancreatico-duodenal vessels** run downwards, and break up on the front of the head (Fig. 925).

The **neck** (Fig. 925) is a thin portion of the gland which lies in front of the portal vein, and connects the head to the body. It is attached on the right to the upper portion of the head, and runs forwards, upwards, and to the left for about 1 inch (25 mm.), and passes into the body.

The neck is about $\frac{3}{4}$ inch (18 mm.) in width, and less than $\frac{1}{2}$ inch (12·5 mm.) in thickness. *In front and to its right* lie the first part of the duodenum and the pylorus; *behind and to the left* it rests upon the beginning of the portal vein, which is formed under cover of its lower border by the union of the splenic and superior mesenteric veins. It has a partial covering of peritoneum on its anterior surface; and its beginning is generally marked off from the head by the gastro-duodenal artery, with its continuation the superior pancreatico-duodenal, which lies in a groove of the gland substance between the head and neck.

As the transverse mesocolon is followed to the right it is, as a rule, found to terminate near the neck of the pancreas (Fig. 925). Beyond this, the posterior surface of the colon is connected

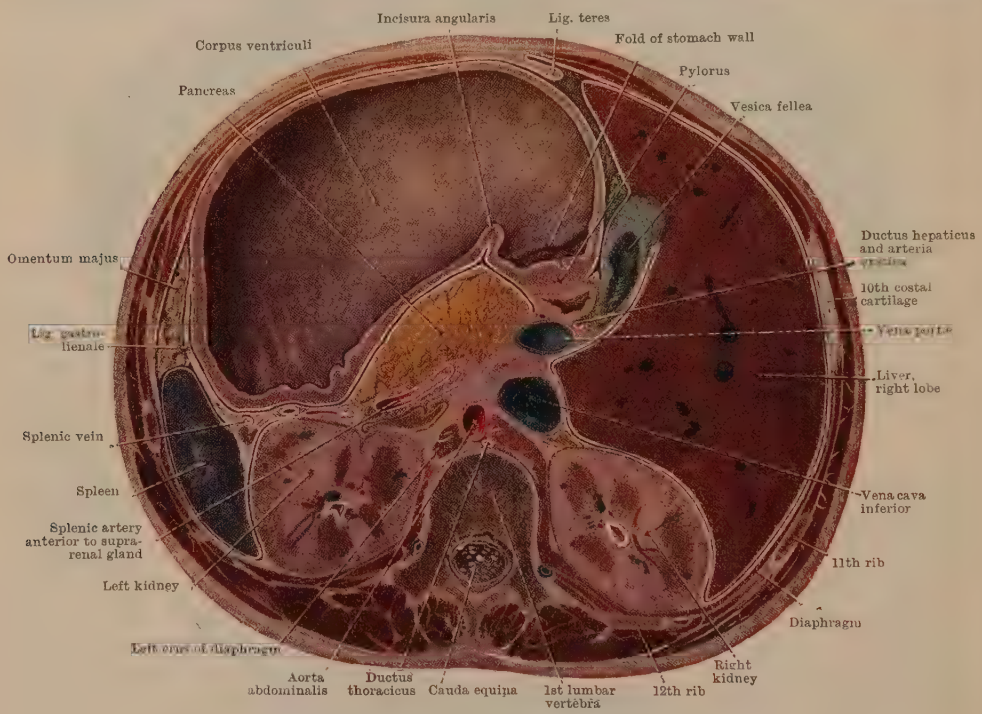

FIG. 926.—TRANSVERSE SECTION OF THE TRUNK AT THE LEVEL OF THE FIRST LUMBAR VERTEBRA.
Showing relations of stomach, pancreas, kidneys, etc. From a subject ten years old.

by areolar tissue to the anterior aspect of the head of the gland. Below the level of the colon the head is covered by the continuation downwards of the peritoneum from the inferior surface of that gut. Often, however, the transverse mesocolon is continued to the right as far as the right colic flexure, and the anterior surface of the head is then completely covered by peritoneum.

Corpus Pancreatis.—The **body** is of a prismatic form, largest where it lies in front of the left kidney, and usually somewhat tapering towards the tail (Fig. 927). From the neck it runs backwards and to the left across the front of the left kidney, beyond which its extremity or tail comes in contact with the spleen. When hardened *in situ* it presents three surfaces—anterior, inferior, and posterior—all of which are of nearly equal width (namely, about $1\frac{1}{4}$ inches: 31 mm.).

Facies Anterior.—The **anterior surface** is widest towards the left end; it looks upwards and forwards (Fig. 926), and forms a considerable portion of the stomach-bed. This surface is completely covered by peritoneum, derived from the posterior wall of the bursa omentalis, which latter separates the pancreas from the posterior surface of the stomach. Towards its right extremity it usually presents an elevation or prominence where the body joins the neck. This projects against the back of the lesser omentum when the stomach is distended, and is consequently known as the **tuber omentale**.

Facies Inferior.—The **inferior surface** looks downwards and slightly forwards. It is completely covered by peritoneum, continuous with that forming the posterior layer of the transverse meso-colon (Fig. 912). It lies in contact with the duodeno-jejunal flexure towards its right end, with the left flexure of the colon near its left end, and with a mass of small intestine (jejunum, which is always found packed in beneath it) in the rest of its extent.

Facies Posterior.—The **posterior surface** looks directly backwards, and is entirely destitute of peritoneum. It is connected by areolar tissue to the posterior abdominal wall with the organs lying upon it. From right to left these are: the aorta with the origin of the superior mesenteric artery, the left renal vessels, the left supra-renal gland, and the left kidney. In addition, the splenic artery runs its tortuous course to the left along the superior border of the pancreas, whilst the splenic vein runs, behind the gland, at a lower level than the artery.

The three surfaces of the body of the pancreas are separated by three borders. The **margo anterior** is the most prominent, and gives attachment to the transverse mesocolon (Fig. 912). It is, as it were, squeezed forward, by the pressure of the stomach above and the small intestine below, into the interval between these two sets of viscera, thus following the line of least resistance (Cunningham). Towards the neck this border is no longer prominent, but becomes rounded off, so that here the superior and inferior surfaces are confluent.

The cœliac artery projects over the **margo superior**, and sends its hepatic branch to the

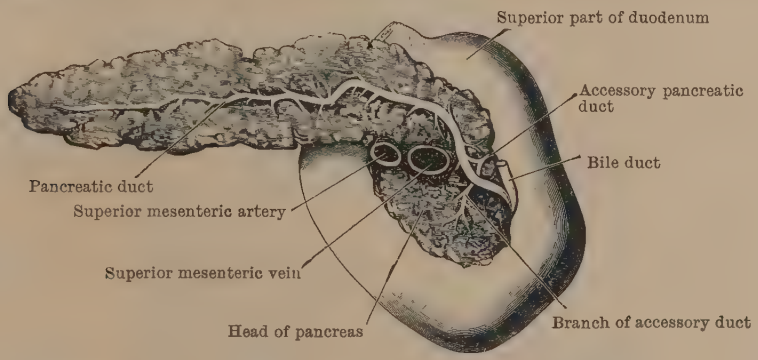

Fig. 927.—Posterior Aspect of the Pancreas and Duodenum, with the pancreatic duct exposed. The superior mesenteric vessels also are shown in section, passing forwards, surrounded by the recurved portion of the head of the pancreas.

right, resting upon it, whilst the splenic artery runs to the left along it (Fig. 925). The **margo inferior** calls for no special description.

Cauda Pancreatis.—The **tail of the pancreas** is the somewhat pointed left end of the body, in contact with the inferior portion of the gastric surface of the spleen. It usually presents an abrupt, blunt ending, or it may be elongated and narrow. It is in near relation below with the left flexure of the colon (Fig. 912).

Ducts of the Pancreas.—Almost invariably two ducts are found in the interior of the pancreas—the **ductus pancreaticus [Wirsungi]** or **pancreatic duct** proper and the **ductus pancreaticus accessorius [Santorini], accessory pancreatic duct.**

The **pancreatic duct** begins near the tip of the tail by the union of small ducts from the lobules forming that part of the organ. From there it pursues a rather sinuous or zigzag course (Fig. 927) through the axis of the gland, at first running transversely to the right, until the neck is reached, then it bends downwards into the head, approaches the descending part of the duodenum, and meets the bile-duct (see p. 1194).

In its course through the gland the pancreatic duct receives numerous tributaries, which join it, as a rule, at a right angle. The tributaries, as well as the main duct itself, are easily recognised by the whiteness of their walls, which contrasts with the darker colour of the gland tissue. The main duct receives tributaries from all portions of the pancreas, and towards its termination attains a considerable size (namely, $\frac{1}{10}$th to $\frac{1}{6}$th of an inch—2·5 to 4 mm.—when flattened out, or somewhat larger than a crow quill).

The **pancreatic accessory duct** (**Santorini**) is a small and variably developed duct (Fig. 927) which opens into the duodenum about $\frac{3}{4}$ of an inch above and somewhat anterior to the pancreatic duct. From the duodenum it runs to the left and downwards, and soon divides into two or more branches, one of which joins the pancreatic duct, the others pass down and receive tributaries from the lower part of the head. It is generally supposed that the current flows from this into the main duct, and not into the duodenum, as a rule, except in early life.

Physical Characters and Structure of the Pancreas.—The lobules of the pancreas resemble closely in structure the lobules of the salivary glands, and show a similar arrangement of secreting tubules and ducts. The tubules are lined with short cylindrical cells, with a deeply placed nucleus, and often showing granules in the free margin. In the centre of the base of the tubule are found spindle-shaped epithelial cells, termed the centro-acinar cells.

In addition, however, each lobule contains additional structures, known as **Langerhans' islets.** These are masses of cell cords, showing no glandular structure, and not connected with the ducts, lying between the gland acini. They are believed to produce an internal secretion.

Variations.—The chief variations found are:—(1) A separation of the part of the head, known as the uncinate process, which then forms a *lesser pancreas.* (2) A growth of the pancreas around the duodenum, which it may practically encircle for a short part of its course. And (3) an opening of its duct into the duodenum, independently of the bile duct. An *accessory pancreas* (pancreas accessorium) is also sometimes found in the wall of the stomach or of the jejunum. Diverticula of the duodenum, already described (p. 1180), ought perhaps to be mentioned in this connexion.

Vessels.—The **arteries** of the pancreas are: (1) The **superior pancreatico-duodenal,** a branch of the gastro-duodenal artery, which runs down on the front of the head (Fig. 925), sending branches laterally to the duodenum, as well as numerous twigs into the substance of the pancreas. (2) The **inferior pancreatico-duodenal,** a branch of the upper part of the superior mesenteric artery; or from the root of one of the rami jejunales; it runs upwards and to the right across the back of the head, and sends branches to it and to the duodenum, one of which runs between the head and the duodenum. These two pancreatico-duodenal arteries anastomose around the inferior border of the head. (3) **Pancreatic rami** from the **splenic artery,** are several (3 to 5) fair-sized branches which come off from the splenic as it runs behind the superior border of the gland; they enter the pancreas immediately, and traverse its substance from above downwards, some sending branches in both directions along the course of the pancreatic duct.

The **veins** are: (1) The *pancreatico-duodenal veins* (Fig. 925), of which some pass downwards and to the left, on the front of the head, and join the superior mesenteric; while others cross the back of the head, and open into the superior mesenteric; (2) several small pancreatic veins which join the splenic.

The **lymph vessels** pass chiefly with the splenic lymph vessels to the cœliac glands; some also are connected with a few glands which lie near the upper end of the superior mesenteric vessels. All the lymph of the organ passes ultimately to the cœliac glands.

The **nerves,** which are almost entirely non-medullated, come from the plexus cœliacus, through the hepatic and splenic plexuses.

INTESTINUM TENUE MESENTERIALE.

Intestinum Jejunum et Intestinum Ileum.

The succeeding portions of the small intestine do not lie on the posterior abdominal wall, but hang freely from it by a lamina of connective tissue, containing the blood-vessels, lymph vessels, and nerves, and covered on each side by peritoneum, and termed the mesentery. Hence the name of "intestinum tenue mesenteriale" which is given to them.

The part of the tube to which the mesentery is connected is known as the mesenteric or attached border; the opposite side is the free border.

Mesenterium.—The **mesentery** is a broad fan-shaped fold, composed of two layers of peritoneum, which connects the small intestine to the posterior wall of the abdomen. The long free border of the fold contains the intestine within it (Fig. 891). The other, or attached border, known as the **radix mesenterii** (*root of the mesentery*), is comparatively short, being only 6 or 7 inches long; but it is much thicker than the part near the gut, for it contains between its layers a considerable amount of fatty extra-peritoneal tissue, in addition to the large vascular trunks passing to the intestine. The root is attached to the posterior abdominal wall along an oblique line, extending approximately from the left side of the second lumbar vertebra to the right iliac fossa (Fig. 928). In this course its line of attachment passes from the duodeno-jejunal flexure down over the front

of the terminal part of the duodenum, then obliquely across the aorta, the inferior vena cava, the right ureter, and psoas major muscle, to reach the right iliac region.

The unattached border of the mesentery is frilled out to an enormous degree, so that, while the root measures but 6 or 7 inches, the free border is extended to some 20 feet, thus resembling a fan, one border of which may be twenty or thirty times as long as the other. The length of the mesentery, measured from its root to the attached edge of the intestine directly opposite, usually measures at its longest part about 6 inches (8 or 9 inches, Treves and Lockwood).

Its longest part goes to the portion of the small intestine situated between two points, one six feet, the other eleven feet from the duodenum (Treves).

Between the two layers of the mesentery (Fig. 928) are contained (*a*) the jejunal and ileal branches of the superior mesenteric vessels, accompanied by the

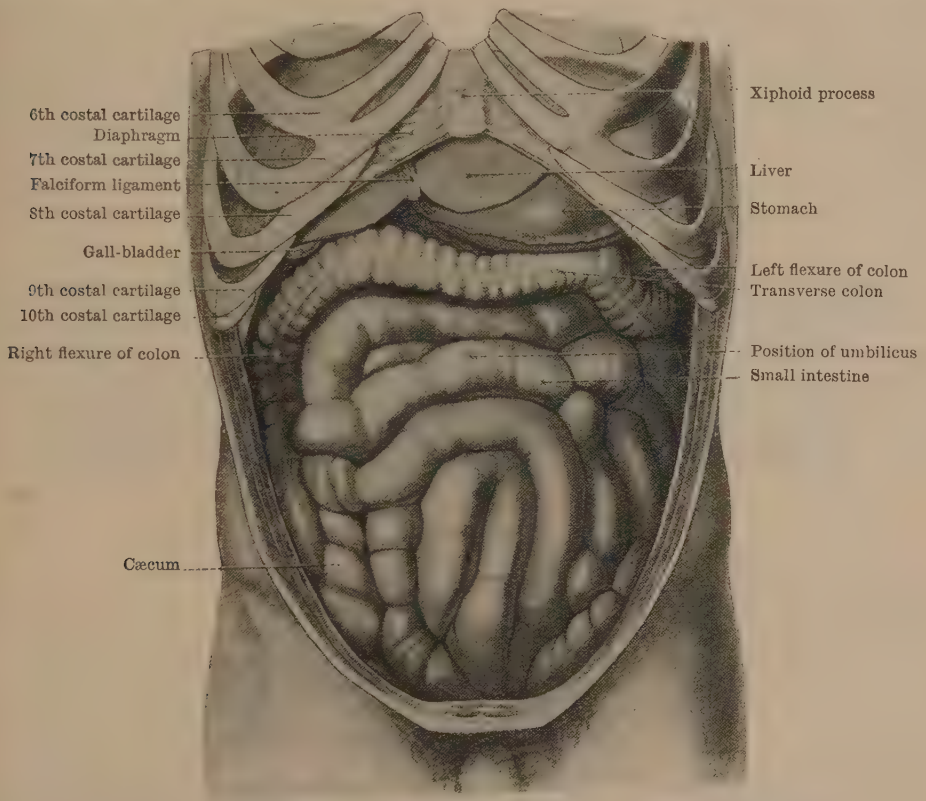

FIG. 928.—THE ABDOMINAL VISCERA, AFTER REMOVAL OF THE OMENTUM MAJUS AND THE LIG. GASTROCOLICUM.

mesenteric nerve plexus and lymph vessels; (*b*) the mesenteric lymph glands, which vary from 40 to 150 in number; (*c*) a considerable amount of fatty connective tissue, continuous with the extra-peritoneal areolar tissue; and (*d*) the intestine itself.

The peritoneum from the right side of the mesentery passes out on the posterior abdominal wall to clothe the ascending colon, and, above, it is connected by a fold with the transverse mesocolon. That of the left side, similarly, passes across the parietes to the descending and iliac portions of the colon.

The mesentery begins above, immediately beyond the ending of the duodenum—that is, in the angle of the duodeno-jejunal flexure—and it ends below in the angle between the ileum and ascending colon. It is very short at each end, but soon attains the average length.

The mesentery is of such a length that the coils are able to move about freely in the abdominal cavity, and consequently the position occupied by any portion of the tube, with the exception of the beginning of the jejunum and the ending of the ileum, can never be stated with certainty. Nevertheless, it may be said that,

in general, the jejunum occupies the superior and left portions of the cavity below the stomach, the ileum the inferior and right divisions, its terminal part almost always lying in the pelvis, just before it joins the large gut.

According to Mall, the most usual arrangement is to find the proximal coils of the jejunum on the left side, and high up. Then the tube crosses the vertebral column below the duodenum, and a few coils are placed on the right side. It then crosses to the left side again, and several coils are formed, some of which may descend into the pelvis. Thence it passes again to the right side, where it is coiled up, and then finally descends into the pelvis. The terminal portion almost always lies in the pelvis, just before it ascends to join the large intestine.

Whilst the root of the mesentery pursues at its attachment an almost straight line from one end to the other, if cut across a very short distance from the posterior abdominal wall, it will here be found to form a wavy or undulating line. Further away still this condition becomes more and more marked; and finally, if the bowel is removed by cutting through the mesentery close to its attachment to the intestinal wall, it will be seen that its free edge is not only undulating, but is frilled or plaited to an extreme degree. When shown in this way, it is found that the plaiting or folding is not quite indiscriminate, but that the main folds, of which there are usually six, run alternately to the right and left. As a rule, the first fold runs to the left from the duodeno-jejunal flexure, and goes to a coil of jejunum which lies under the transverse mesocolon, and helps to support the stomach. The second fold passes to the right, the third to the left, and so on up to the fifth and sixth, which are usually small. From the margins of these primary folds secondary folds project in all directions, and from these again even a third series may be formed.

This order is of course by no means constant, but if the intestine is removed from a hardened body in the way suggested, without disturbing the mesentery, it will be found to be arranged with more or less regularity, on some such plan as that indicated.

Differences between Jejunum and Ileum.—If the small intestine is followed down from the duodenum to the cæcum no noticeable change in appearance will be found at any one part of its course, to indicate the transition from jejunum to ileum; for the one passes insensibly into the other. Nevertheless, a gradual change takes place, and if typical parts of the two, namely, the upper portion of the jejunum and the lower portion of the ileum, are examined, they will be found to present characteristic differences, which are set forth in the following table:—

Jejunum.	Ileum.
Wider, $1\frac{1}{2}$ to $1\frac{1}{4}$ inch in diameter.	Narrower, $1\frac{1}{4}$ to 1 inch in diameter.
Wall, thicker and heavier.	Wall, thinner and lighter.
Redder and more vascular.	Paler and less vascular.
Plicæ circulares, well developed.	Plicæ circulares, absent or very small.
Noduli lymphatici aggregati [Peyeri], few and small.	Noduli lymphatici aggregati [Peyeri], large and numerous.

The villi are also said to be shorter and broader in the jejunum, more slender and filiform in the ileum (Rauber).

The terminal portion of the ileum, after crossing the margin of the superior aperture of the pelvis minor, runs upwards, and also slightly backwards and to the right, in close contact with the cæcum, until the ileo-cæcal orifice is reached.

Diverticulum Ilei (O.T. **Meckel's Diverticulum**).—This is a short finger-like protrusion which is found springing from the lower part of the ileum in a little over 2 per cent of the bodies examined. It is usually about 2 inches long, and of the same width as the intestine from which it comes off. Most commonly it is found about $2\frac{3}{4}$ feet from the valvula coli, and opposite the original termination of the superior mesenteric artery. As a rule, its end is free; but occasionally it is adherent either to the abdominal wall, the adjacent viscera, or the mesentery, and in such cases it may be the cause of strangulation of the intestine.

The diverticulum is due to the persistence of the proximal portion of the vitelline (or vitello-intestinal) duct, which connects the primitive intestine of the embryo with the yolk sac. In shape it may be cylindrical, conical, or cord-like, and it may present secondary diverticula near its tip. It arises most frequently from the free border of the intestine, but it sometimes comes off from the side. It runs at right angles to the gut most commonly, but it may assume any direction, and it is often provided with a mesentery. In 3302 bodies specially examined with reference to its existence, it was present in 73, or 2·2 per cent, and it appeared to be more common in the male than in the female. In 59 out of the 73 cases its position with reference to the end of the ileum was examined: its average distance from the ileo-cæcal valve was $32\frac{1}{2}$ inches measured along the gut, the greatest distance being 12 feet, and the smallest 6 inches. In 52 specimens the average length was 2·1 inches, the longest being $5\frac{1}{4}$ inches, the shortest $\frac{1}{2}$ inch.

The diameter usually equals that of the intestine from which it springs; but occasionally it is cord-like, and pervious only for a short way; on the other hand, it may attain a diameter of 3¾ inches.

Structure (Fig. 906).—The **tunica serosa** is complete in all parts of the jejunum and ileum. The **tunica muscularis** is thicker in the jejunum, and grows gradually thinner as it is traced down along the ileum. The **tela submucosa** contains the bases of the solitary nodules, but otherwise calls for no special remark. The **tunica mucosa** is thicker and redder above in the jejunum, thinner and paler in the ileum. It is covered throughout by villi intestinales, which are shorter and broader in the jejunum, longer and narrower in the ileum. In its whole extent it is closely set with intestinal glands, and numerous solitary nodules are seen projecting on its surface. Aggregated lymph nodules are particularly large and numerous in the ileum; they are fewer, smaller, and usually circular in the jejunum. Finally, the mucous membrane forms plicæ circulares, which are much more prominent in the jejunum; they are smaller and fewer in the superior part of the ileum, and usually disappear a little below its middle.

INTESTINUM CRASSUM.

The ileum is succeeded by the **intestinum crassum (large intestine)**, which begins on the right side, some 2½ inches below the ileo-cæcal junction, and comprises the following parts: cæcum and processus vermiformis, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, iliac and pelvic colon, rectum and anal canal.

In its course the large bowel is arranged in an arched manner around the small intestine, which lies within the concavity of the curve (Fig. 928).

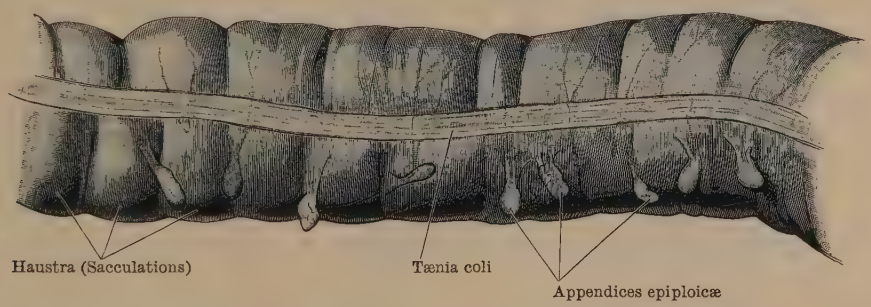

FIG. 929.—LARGE INTESTINE.

A piece of transverse colon from a child two years old. The three chief characteristics of the large intestine—sacculations, tæniæ, and appendices epiploicæ—are shown.

In *length*, the great intestine is equal to about one-fifth of the whole intestinal canal, and usually measures between 5 and 5½ feet (1–3 m.). Its *breadth* is greatest at the cæcum, and from this—with the exception of a dilatation at the rectum—it gradually decreases to the anus. At the cæcum it measures, when distended, about 3 inches (75 mm.) in diameter; beyond this it gradually diminishes, and measures only 1½ inches (37 mm.) or less in the descending and iliac divisions of the colon.

The large intestine, with the exception of the rectum and vermiform process, may be easily distinguished from the regularly cylindrical small intestine by (*a*) the presence of three longitudinal bands—the **tæniæ coli**—running along its surface (Fig. 929); (*b*) by the fact that its walls are sacculated; and (*c*) by the presence of numerous little peritoneal processes, known as **appendices epiploicæ**, projecting from its serous coat. In addition, the larger intestine is usually wider than the small, but reliance cannot be placed on this character, for the jejunum is often—indeed, generally—wider than the empty and contracted descending colon. The internal surface of the mucous membrane shows no villi.

Tæniæ Coli.—The longitudinal muscular fibres do not form a complete layer, continuous all round the tube, but, on the contrary, are arranged in three separate bands, known as the **tæniæ coli**. These bands, which are about ¼ inch (6 mm.) wide, begin at the base of the vermiform process, and run along the surface of the gut at nearly equal distances from one another as far as to the rectum. There they spread out and form a layer of longitudinal muscular fibres, which is

continuous all round the tube (see p. 1215). The bands are about one-sixth shorter than the intestine to which they belong; consequently, in order to accommodate the bowel to the length of the tæniæ, the gut is tucked up (Fig. 929), and three rows of pouches or saccules are produced, along the length of the tube, between the tæniæ. If the tæniæ are dissected off, the sacculations largely disappear, the intestine becomes cylindrical, and at the same time about one-sixth longer.

The **appendices epiploicæ** (Fig. 929) are little processes or pouches of peritoneum, generally more or less distended with fat, which project from the serous coat along the whole length of the large intestine, with the exception of the rectum proper.

When the interior of a piece of distended and dried large intestine is examined, its saccules appear as rounded pouches, **haustra**, separated by crescentic folds, **plicæ semilunares coli**, corresponding to the creases on the exterior separating the saccules from one another.

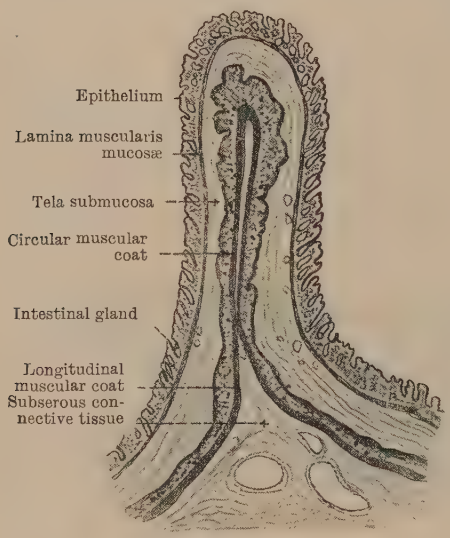

FIG. 930.—TRANSVERSE SECTION OF A PLICA SEMILUNARIS COLI.

The plicæ semilunares of the colon are made up of a double fold of mucous membrane containing a fold of the muscular coats of the intestine as well as connective tissue, and each extends over only one-third of the circumference of the intestine, between the tæniæ.

The position of the three tæniæ on the intestines is as follows: On the ascending, descending, and iliac colons one tænia lies on the anterior aspect of the gut, and two on the posterior aspect, namely, one to the lateral side (postero-lateral), the other to the medial side (postero-medial). It is chiefly along the first of these (the anterior) that the appendices epiploicæ are found. On the transverse colon their arrangement is different, but is rendered exactly similar by turning the great omentum, with the colon, up over the thorax. On the transverse colon in the natural position, the anterior tænia of the ascending and descending colons becomes the posterior (or postero-inferior) termed *tænia libera*, the postero-lateral becomes anterior or *tænia omentalis*, and the postero-medial becomes superior in position and is termed *tænia mesocolica*. The anterior and postero-lateral tæniæ of the iliac colon pass below on to the front of the pelvic colon and rectum.

In formalin-hardened bodies portions of the large intestine, but particularly of the descending and sigmoid colons, are often found fixed in what appears to be a state of contraction, when they are reduced to a diameter of about $\frac{5}{8}$ or $\frac{3}{4}$ of an inch (16 to 19 mm.). Under similar conditions parts of the small intestine are found correspondingly reduced.

The appendices epiploicæ, although generally said to be absent in the fœtus, can be distinctly seen as early as the seventh month, but at this time they contain no fat.

Structure of the Large Intestine.—The **tunica serosa** is complete on the vermiform process, cæcum, transverse colon, and pelvic colon; incomplete on the ascending, descending, and iliac divisions of the colon and on the rectum. It will be described in detail with each of these portions of the intestine.

The **tunica mucosa** is of a pale, or yellowish, ash colour in the colon, but becomes much redder in the rectum. Unlike that of the small intestine, its surface is smooth, owing to the absence of villi, but it is closely studded with the orifices of numerous large intestinal glands. Solitary lymph nodules are also numerous, particularly in the vermiform process (Fig. 930).

Vessels and Nerves.—The cæcum and vermiform process receive their blood from the **ileo-colic artery**; the ascending colon from the **right colic artery**; and the transverse colon from the **middle colic artery**, which lies in the transverse mesocolon. These are all branches of the **superior mesenteric**. The descending colon is supplied by the **left colic**, and the iliac and pelvic colons by the **sigmoid arteries**, branches of the **inferior mesenteric**. The rectum derives its blood from the three **hæmorrhoidal arteries**, which will be described with that division of the gut.

The **veins** correspond largely to the arteries, and join the inferior and superior mesenteric vessels, which send their blood into the portal vein.

The **lymph vessels** of the large intestine arise from plexuses in the submucous and subperitoneal coats, as in other parts of the alimentary canal.

The deeper vessels escape chiefly along the entering blood-vessels, those from the lateral aspects passing behind the intestine.

The vessels pass medially to a series of glands lying along the medial border of the intestine ("paracolic" glands (Jamieson)); thence they pass along the lines of the main arteries, passing then to glands disposed at intervals about these vessels (intermediate and main glands). The lymph vessels from the lower half of the descending colon, and from the iliac and pelvic colons, join the left lymph trunk of the lumbar glands. Those of the rectum and cæcum will be described later.

Nerves.—The nerves come from the superior mesenteric plexus, an offshoot of the cœliac plexus, and from the inferior mesenteric, a derivative of the aortic plexus. The arrangement is similar to that of the nerves of the small intestine.

INTESTINUM CÆCUM AND PROCESSUS VERMIFORMIS.

Intestinum Cæcum.—After leaving the pelvic cavity, as already described, the terminal portion of the small intestine passes upwards, backwards, and to the right, and opens, by the ileo-cæcal orifice, into the large intestine some 2½ inches from its lower end. The portion of the large gut which lies below the level of this orifice is known as the **intestinum cæcum.** *In shape* (Fig. 931) it is a wide, asymmetrical, or lop-sided cul-de-sac, furnished with the tæniæ and sacculations usually found in the large intestine. Its lower end or *fundus* is directed downwards and medially, and usually rests on the right psoas major muscle, close to the brim of the pelvis; whilst the opposite end is directed upwards and laterally, and is continued into the ascending colon.

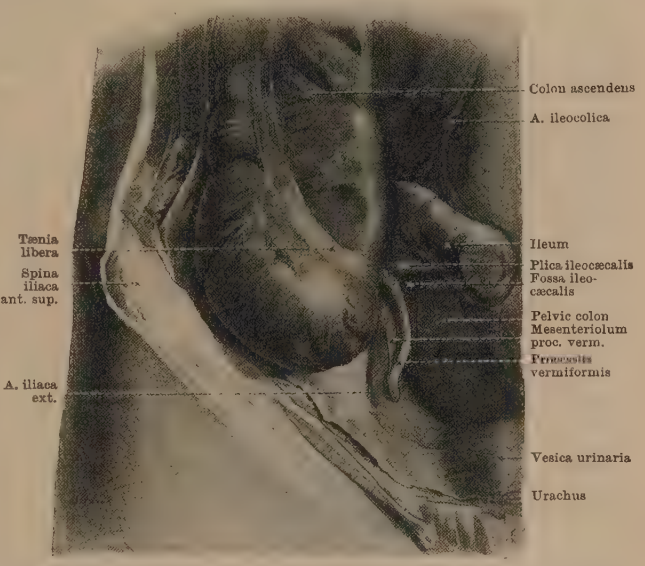

FIG. 931.—THE CÆCUM AND VERMIFORM PROCESS FROM THE FRONT.

Its asymmetrical form is due to the fact that the lateral and medial portions of the organ undergo an unequal development in the child. The medial (or medial and posterior) section lags behind, whilst the lateral (or lateral and anterior) division grows much more rapidly, and, projecting downwards, soon comes to form the inferior end or fundus of the cæcum. As a result the original extremity of the gut, with the vermiform process springing from it, is hidden away behind and to the medial side of the fundus.

In *length* the distended cæcum usually measures about 2½ inches (60 mm.); whilst its *breadth* is usually more, and averages about 3 inches (75 mm.).

Position. — It is usually situated almost entirely within the right iliac region of the abdomen, immediately above the lateral half or third of the inguinal ligament; but its inferior end projects medially in front of the psoas major and reaches the hypogastrium (Fig. 931). On the other hand, it is sometimes found high up in the right lumbar region (owing to the persistence of the fœtal position), or hanging over the pelvic brim and dipping into the pelvic cavity to a varying extent.

In the great majority of cases the cæcum is completely covered with peritoneum on all aspects, and lies quite free in the abdominal cavity. In a small proportion, namely, about 6 or 7 per cent of bodies, the posterior surface (probably as a result of adhesions) is not completely covered, but over a greater or less portion of its extent is bound down to the posterior abdominal wall by connective tissue.

Relations.—*Posteriorly*, the cæcum rests on the ilio-psoas muscle; generally, too, on the vermiform process and the femoral nerve. *Anteriorly*, it usually lies in contact with the omentum and anterior abdominal wall; but when the cæcum

is empty, the small intestine intervenes. Its *lateral side* is placed immediately above the lateral half or third of the inguinal ligament (Fig. 931), whilst the *medial side* has the termination of the ileum lying in contact with it. On the medial and posterior aspects, but more on the former than the latter, the small intestine joins the cæcum. On the same aspect, and usually from 1 to 1½ inches (25 to 37 mm.) lower down, the vermiform process comes off.

The *interior* of the cæcum corresponds in general appearance to that of the large intestine; but it presents two special features on the posterior part of its medial wall, namely, the **ileo-cæcal orifice**, guarded by the **valvula coli** (O.T. **ileo-cæcal valve**), and below that the small opening of the **processus vermiformis**, both of which call for further notice.

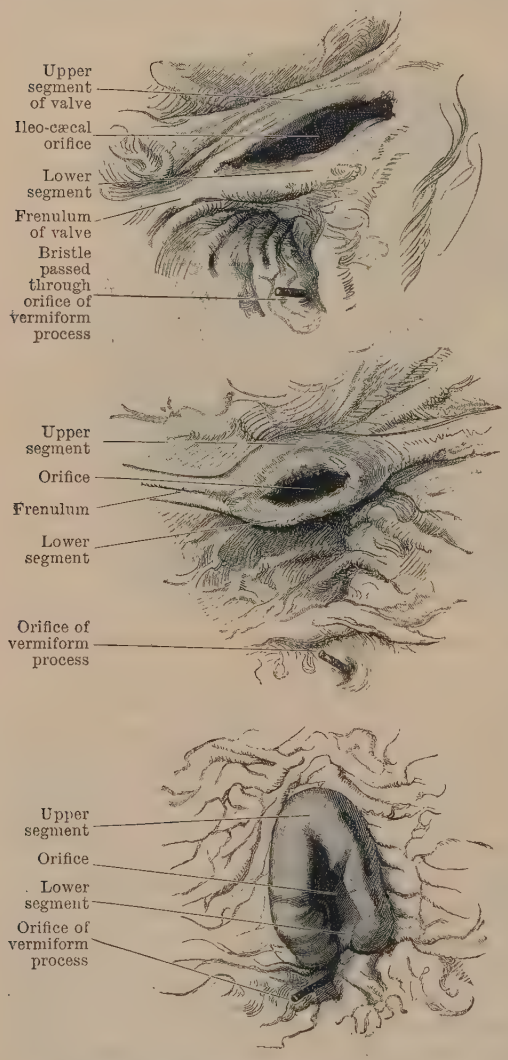

FIG. 932. — THREE FORMS OF VALVULA COLI, from bodies hardened by intra-vascular injections of formalin.

The hardening was not so complete in the case of the highest of the three valves represented. In each a bristle is passed through the orifice of the vermiform process.

Valvula Coli (O.T. **Ileo-cæcal Valve**).—Where the ileum enters the large intestine, the end of the small gut is, as it were, thrust through the wall of the large bowel, carrying with it certain layers of that wall, which project into the cæcum in the form of two folds, lying respectively above and below its orifice, and constituting the two segments of the valve (Fig. 933). The peritoneum and longitudinal muscular fibres of the bowel take no part in this infolding; on the contrary, they are stretched tightly across the crease produced on the exterior by the inversion, and thus serve to preserve the fold and the formation of the valve.

As seen from the interior, in specimens which have been distended and dried (Fig. 933), the valve is made up of two crescentic segments—a superior, **labium superius**, in a more or less horizontal plane; and an inferior, **labium inferius**, which is larger, placed in an oblique plane, and sloping upwards and inwards (*i.e.*, towards the cavity of the cæcum). Between the two segments is situated the slit-shaped opening, which runs in an almost antero-posterior direction, with a rounded anterior and a pointed posterior extremity (Fig. 932). At each end of the orifice the two segments of the valve meet, unite, and are then prolonged around the wall of the cavity as two prominent folds—the **frenula valvulæ coli**. It is thought that when the cæcum is distended, and its circumference thereby increased, these frenula are put on the stretch, and, pulling upon the two segments of the valve, they bring them into apposition, and effect the closure of the orifice.

The **position of the valvula coli**, in the average condition, may be indicated on the surface of the body by the point of intersection of the intertubercular and vertical lateral lines. A point 1 to 1½ inches (2·5 to 3·7 cm.) lower down would correspond to the **orifice of the vermiform process**.

In bodies hardened *in situ* with formalin, the valve and orifice present a different appearance (see Fig. 932, in which three different forms of hardened valves are shown), suggesting, much more closely than in the dried state, the appearance of telescoping or inversion mentioned above. In them also the two segments of the valve are much thicker and shorter, but they can always be distinguished, and are found to bear the same relation to one another as in the dried condition, although this may be obscured by foldings or rugæ. The aperture may be slit-like or rounded, with sloping or funnel-shaped edges; the frenula are not so prominent at times; but the whole valve projects much more abruptly into the cavity of the cæcum than in the distended and dried specimen.

Structure of the Valvula Coli.—Each labium of the valve consists of two layers of mucous membrane, with the submucosa and the circular muscular fibres between, all of which are continuous with those of the ileum on the one hand and of the large intestine on the other. The surface of each labium turned towards the small intestine is covered with villi, and conforms in the structure of its mucous membrane to that of the ileum; whilst the mucous membrane of the opposite surface resembles the mucous coat of the large bowel.

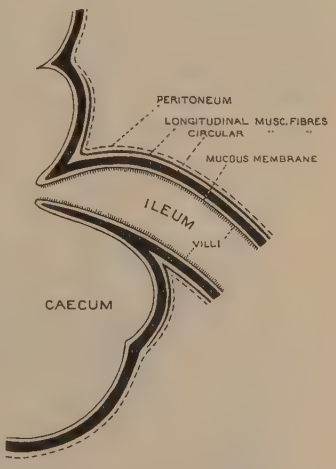

Fig. 933.—Diagrammatic Section through the Junction of the Ileum with the Cæcum, to show the Formation of the Valvula Coli.

In the dried specimen the superior labium usually projects further into the cavity of the cæcum than the inferior, so that the aperture appears to be placed between the edge of the inferior segment and the inferior surface of the superior.

There is little doubt that the efficiency of the valvula coli is largely due to the oblique manner in which the ileum enters or invaginates the large intestine; this oblique passage alone, as in the case of the ureter piercing the wall of the bladder, would probably be sufficient to prevent a return of the cæcal contents. In the great majority of cases, when in position within the body, the ileum is perfectly protected from such a return, although when the parts are removed, and then distended with fluid, this fluid often passes through the valve, and reaches the small intestine. Still, the efficiency of such a test, applied when the parts are deprived of their natural supports, cannot be relied upon.

The size of the segments of the valve, as seen in the dried condition, varies considerably; they are sometimes very imperfect; and even the absence of both has been recorded. But here again there is danger of falling into error, through examining the parts under such artificial conditions.

Types of Cæcum.—Three chief types of cæcum may be distinguished—the *fœtal type*, conical in shape and nearly symmetrical, with the inferior end gradually passing into the vermiform process; the *infantile*, in which the passage from the cæcum to the vermiform process becomes more abrupt, the lateral wall more prominent, and the whole sac more asymmetrical; and the lop-sided *adult form*, as described above, which is the condition found in 93 or 94 per cent of adults.

Structure.—Nothing in the arrangement of the mucous and submucous coats calls for special notice. The tæniæ or longitudinal bands of the muscular coat all spring from the base of the vermiform process (Fig. 931); the anterior runs up on the front, medial to the main prominence of the cæcum; the postero-lateral runs up behind this prominence; whilst the postero-medial passes directly upwards behind the ileum (Fig. 934). The longitudinal fibres on the superior aspect of the ileum partly join the postero-medial tænia; those on the anterior and posterior aspects join the circular fibres of the large gut.

The serous coat has, in connexion with it, certain folds and fossæ which are described at p. 1208.

Processus Vermiformis (Fig. 934).—The **vermiform process** (O.T. **appendix, or vermiform appendix**) is a worm-like tubular segment which springs from the medial and posterior part of the cæcum about 1 to 1½ inches (2·5 to 3·75 cm.) below the ileo-cæcal orifice. From that point it generally runs in one of three chief directions, namely—(1) over the brim, into the pelvis; (2) upwards behind the cæcum; or (3) upwards and medially, thus pointing towards the spleen; each of which has been considered to be the normal position by one or more observers. In the first of these situations it is quite evident as it hangs over the pelvic brim; in order to expose it in the second, the cæcum must be turned upwards; whilst in the third position it lies behind the end of the ileum and its mesentery, and these must be raised up in order to display it. In addition to the positions just mentioned, it has been found in almost every possible situation in the abdomen which its length and the extent of its mesentery would allow it to attain. In every case the

anterior tænia of the cæcum, which is always distinct, offers the surest guide to the vermiform process, and its base can be located with certainty by following this tænia to the back of the cæcum (Fig. 934).

Its size is almost as variable as its position. Taking the average of numerous measurements, its length may be given as about $3\frac{1}{2}$ inches (92 mm., Berry), and its breadth as $\frac{1}{4}$ inch (6 mm., Berry). On the other hand, it has been found as long as 9 inches (230 mm.), and as short as $\frac{3}{4}$ inch (18 mm.). Even its absence has been recorded (Fawcett), but this must be looked upon as an extremely rare occurrence.

Its *lumen* or *cavity* is variable in its development, and is found to be totally or partially occluded in at least one-fourth of all adult and old bodies examined. It opens into the cavity of the cæcum on its medial, or medial and posterior aspect (Fig. 932), at a point 1 to $1\frac{1}{2}$ inches (25 to 38 mm.) below, and somewhat posterior to the ileo-cæcal orifice. These are the relative positions of the two orifices, as seen from the interior of the cæcum; viewed from the exterior, the base of the vermiform process is within $\frac{3}{4}$ inch of the lower border of the ileum. This apparent difference

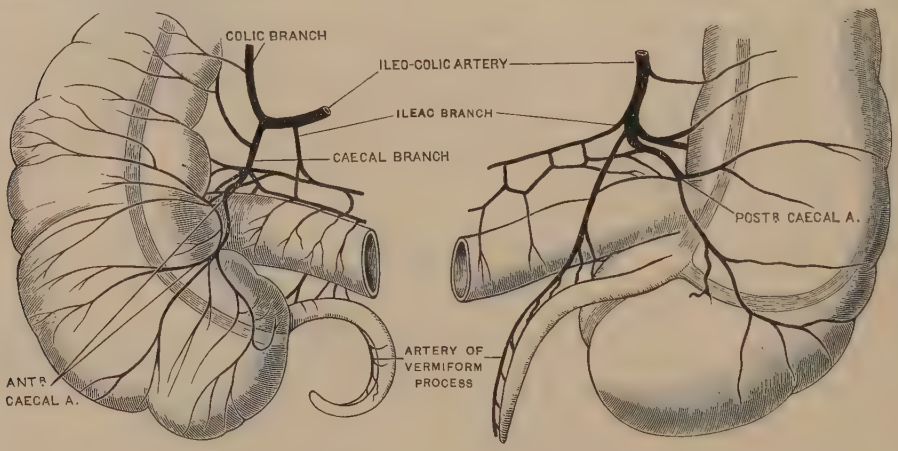

FIG. 934.—THE BLOOD-SUPPLY OF THE CÆCUM AND VERMIFORM PROCESS.

The illustration to the left gives a front view; in that to the right the cæcum is viewed from behind. In the latter the artery of the process, and three tæniæ coli springing from the base of the vermiform process, should be specially noted. (Modified from Jonnesco.)

is due to the fact that the ileum adheres to the medial side of the cæcum for a distance of nearly 1 inch before it opens into it.

The orifice of the vermiform process has a crescentic fold or valve, the **valvula processus vermiformis**, placed at its superior border; but it is probably of very little functional importance, for the aperture of the process is usually so small that its cavity is not likely to be invaded by the contents of the cæcum.

The vermiform process is completely covered with peritoneum, and has a considerable mesentery, the *mesenteriolum processus vermiformis* (O.T. *meso-appendix*), which extends to its tip as a rule, and connects the process to the inferior surface of that part of the mesentery proper which goes to the inferior extremity of the ileum.

The vermiform process is relatively, to the rest of the large intestine, longer in the child at birth than in the adult, the proportion being about 1 to 16 or 17 at birth and 1 to 19 or 20 in the adult. The process attains its greatest length and diameter during adult and middle age, and atrophies slowly after that time. It is said to be slightly longer in the male than in the female.

Total occlusion of its cavity is found in 3 or 4 per cent of bodies; it is then converted into a fibrous cord. Partial occlusion is present in 25 per cent of all cases, and in more than 50 per cent of those over 60 years old, whilst it is unknown in the child. This frequency of occlusion, the physiological atrophy which takes place after middle life, the great variations in length, and other signs of instability, have been considered to point to the retrogressive character of the vermiform process.

A vermiform process is found only in man, the higher apes, and the wombat, although in certain rodents a somewhat similar arrangement exists. In carnivorous animals the cæcum is very

slightly developed; in herbivorous animals (with a simple stomach) it is, as a rule, extremely large. It has been suggested that the vermiform process in man is the degenerated remains of the herbivorous cæcum, which has been replaced by the carnivorous form. Another and perhaps more probable view regards the process as a lymph organ, having the same functions as lymph nodules, and, like these, undergoing degeneration after middle life (Berry).

In the fœtus and child, as well as in the adult with the infantile type of cæcum, the vermiform process springs from the true apex, not from the medial and posterior aspect.

Foreign bodies, although reputed to find their way very easily into the vermiform process, are rarely found there after death. On the other hand, concretions or calculi, formed of mucus, fæces, and various salts, are often present (Berry).

Structure (Fig. 935).—The **tunica serosa** is complete, and forms a perfect investment for the process. The **tunica muscularis**, unlike that of the rest of the large intestine, has a continuous and stout layer of longitudinal fibres, which passes at the root of the process into the three tæniæ coli (Fig. 934). The layer of circular fibres is well developed. The **tela submucosa** is almost entirely occupied by large masses of lymph tissue surrounded by sinus-like lymph spaces. Owing to the large size of these lymph nodules, the areolar tissue of the submucosa is compressed against the inner surface of the muscular coat, and forms a well-marked fibrous ring, which sends processes at intervals between the lymph masses towards the mucous membrane. These lymph nodules, which correspond to solitary lymphoid nodules, have, owing to their great number, been almost completely crushed out of the mucosa (in which they chiefly lie in the intestine) into the submucosa.

The **mucous coat** corresponds to that of the large intestine in its general characters, but the

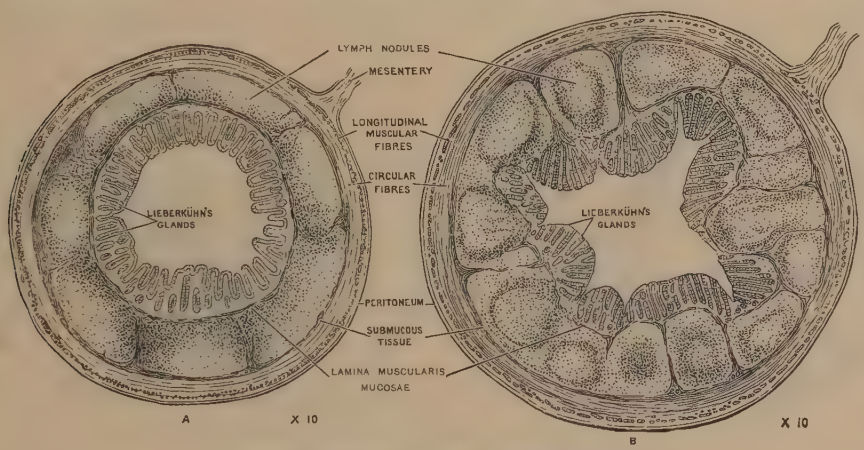

FIG. 935.—STRUCTURE OF THE VERMIFORM PROCESS.

A. From a child two years old. B. From a male, age 56.

It will be observed that the tela submucosa is almost entirely occupied by lymph nodules and patches. The lamina muscularis mucosæ is very faint, and lies quite close to the bases of the intestinal glands. The longitudinal layer of muscular fibres forms a continuous sheet.

intestinal glands are fewer, and irregular in their direction; the lamina muscularis mucosæ is thin and ill-defined; it lies just internal to the lymphoid nodules of the submucosa, and immediately outside the base of the intestinal glands. Some few lymph nodules lie in the mucous coat also.

Blood-vessels of the Cæcum and Vermiform Process (Fig. 934).—These parts are supplied with blood by the **ileo-colic artery**. This gives off, near the upper angle formed by the junction of the ileum with the small intestine—(*a*) an *anterior ileo-cæcal artery*, which passes down on the front of the ileo-cæcal junction to the cæcum, and breaks up into numerous branches for the supply of that part; (*b*) a *posterior ileo-cæcal artery*, similarly disposed on the back; and (*c*) the *artery for the vermiform process*. The last-named branch passes down behind the ileum (Fig. 934), then enters the mesentery of the process, and running along this near its free border, sends off several branches across the little mesentery to the process, before finally ending in it. The course of the artery behind the ileum is said to render it subject to pressure from fæcal masses in that gut, and thus to predispose to an interference with the blood supply of the vermiform process, and to morbid changes in it.

The **lymph vessels** of the cæcum and vermiform process arise mainly from networks in the mucous and serous coats.

The first of these networks communicates with a lymph sinus which is found at the base of the lymph nodules in the process, and the vessels from it pierce the muscular coats, and pass in company with the blood-vessels. They are connected with mucous lymph glands found near the ileo-cæcal junction, especially on the posterior and medial aspect, in the angle between the ileum and colon.

Small isolated glands may be found lying in close contact with the medial part of the cæcum, on its anterior and posterior aspects. From these glands, the lymph stream is directed upwards

and medially towards the cœliac and lumbar glands. The lymph vessels of the vermiform process may also communicate with the lymph nodes in the iliac fossa, and also, it has been stated, with the lymph vessels of the right ovary.

Cæcal Folds and Fossæ.—The peritoneum in the neighbourhood of the cæcum forms certain fossæ, of which the most interesting and important are—(*a*) the fossa cæcalis; (*b*) the recessus ileocæcalis inferior; (*c*) the recessus ileocæcalis superior; and (*d*) the recessus retrocæcalis.

(*a*) The **fossa cæcalis** (Fig. 936, B) is only occasionally present, and can be exposed by turning the cæcum and adjacent part of the ileum upwards. It is a fossa in the parietal peritoneum on the posterior abdominal wall, open above, in which the lower end of the cæcum occasionally lies. It is produced by the *plica cæcalis*, a peritoneal fold which passes from the surface of the iliacus to the right lateral aspect of the cæcum. Two forms, lateral and medial, are described; the first lies behind the lateral part of the ascending colon, immediately above the cæcum; the second behind its medial part. These fossæ are specially interesting because, when present, they frequently lodge the vermiform process (see Fig. 936, B), a condition which is said to favour the production of appendicitis.

(*b* and *c*) **Recessus Ileocæcales and Plica Ileocæcalis.**—If the vermiform process is

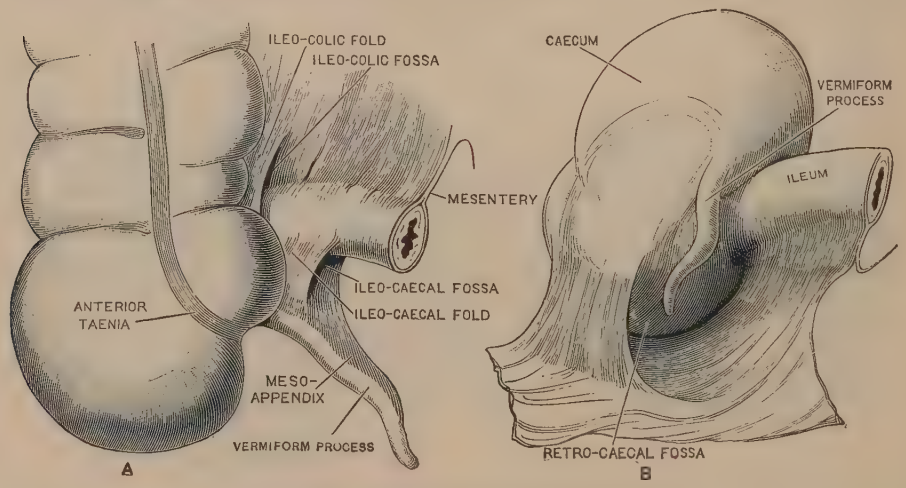

FIG. 936.—THE CÆCAL FOLDS AND FOSSÆ.

In A, the cæcum is viewed from the front; the mesentery of the vermiform process is distinct, and is attached above to the inferior surface of the portion of the mesentery going to the end of the ileum. In B, the cæcum is turned upwards to show a retro-cæcal fossa, which lies behind it and behind the beginning of the ascending colon.

drawn down, and the finger run towards the cæcum, along the *inferior* border of the terminal part of the ileum, its point will generally run into a fossa situated in the angle between the ileum and cæcum (Fig. 936, A), which is known as the *recessus ileocæcalis inferior*. The fold which bounds the fossa in front is the *plica ileocæcalis* (O.T. *the "bloodless fold of Treves"*). It passes from the ileum to the front of the mesentery of the vermiform process, which forms the posterior wall of the fossa.

The plica ileocæcalis contains some unstriped muscle fibres continuous with the longitudinal muscle coat of the cæcum, and some fat especially at its free margin.

The recessus ileocæcalis inferior is bounded above by the lower end of the ileum, to the right by the cæcum, in front by the plica ileocæcalis, behind by the root of the mesenteriolum of the processus vermiformis, while it is open to the left or medially.

Similarly, if the finger is run out along the *superior* border of the ileum towards the cæcum, it will usually lodge in a smaller fossa, the *recessus ileocæcalis superior*, which is bounded in front by a small peritoneal process, the ileo-colic fold (Fig. 936, A), containing the anterior cæcal artery.

The recessus ileocæcalis superior lies at the upper margin of the opening of the ileum into the colon, and is bounded behind by the ileum, to the right by the cæcum.

(*d*) **Recessus Retrocæcalis.**—This is an occasional recess which passes upwards between the ascending colon and the posterior abdominal wall. Its orifice looks downwards or to the left, and lies in the fossa cæcalis behind the cæcum.

COLON.

Colon Ascendens.—The **ascending colon** begins about the level of the intertubercular plane, opposite the ileo-cæcal orifice, where it is continuous with the cæcum. From there it runs upwards and somewhat posteriorly, with a slight concavity to the left, until it reaches the inferior surface of the liver, where it bends forwards and to the left, and passes into the right flexure of the colon (Fig. 937). In its course it lies in the angle between the quadratus lumborum and the more prominent psoas major medially.

It is situated chiefly in the right lumbar region, but it extends slightly into the hypochondrium above; and, although it usually begins about the level of the intertubercular plane, still with a low position of the cæcum it will extend further down, and may occupy a considerable part of the iliac region.

Its *length* is extremely variable, depending upon the extent to which the cæcum has descended from the position it occupied during development, viz., in contact with the under surface of the liver.

It is from 5 to 8 inches long, and it is wider and more prominent than the descending colon. It generally presents several minor curves or flexures, and it often has the appearance of being pushed into a space which is too short to accommodate it.

Relations.—*Anteriorly*, it is usually in contact with the abdominal wall, but the small intestine frequently intervenes, particularly above. To its *medial side* lie the coils of the small bowel and the psoas major; to the *lateral side* is the side wall of the abdomen. Its *posterior surface*, which is free from peritoneum as a rule (Fig. 925), is connected by areolar tissue to the iliacus muscle as far up as the crest of the ilium, to the quadratus lumborum above that, and finally to the inferior part of the right kidney.

In the great majority of cases only the two sides and the anterior surface are covered with peritoneum, the posterior surface being destitute of a serous coat (Fig. 925). In a small proportion of bodies, however, the ascending colon is provided with a complete peritoneal coat and a mesentery, but this latter is so short that it admits of but a slight amount of movement in the gut.

On the lateral aspect of the cæcum and colon there are occasionally found small peritoneal pockets termed **recessus paracolici.**

Like the cæcum, the ascending colon is frequently found distended with gas or fæces after death, hence in part its large size and prominence as compared with the descending colon, which is generally empty.

Flexura Coli Dextra.—The **right** (O.T. **hepatic**) **flexure of the colon** is the bent piece of the large intestine between the end of the ascending colon and the beginning of the transverse colon (Figs. 912 and 937).

When the ascending colon reaches the inferior surface of the liver, it bends—usually acutely, sometimes obtusely—forwards and to the left on the anterior surface of the right kidney, and on reaching the front of the descending portion of the duodenum, passes into the transverse colon.

The flexure is placed between the descending duodenum medially and the anterior thin margin of the liver, or the side wall of the abdomen, laterally; above, it corresponds to the colic impression on the liver, and posteriorly it rests on the kidney. Its peritoneal relations are similar to those of the ascending colon.

Colon Transversum.—This is the long and looped portion of the large intestine which lies between the right and left flexures. It begins at the end of the right flexure, at the point where the colon passes forwards from the anterior surface of the kidney, and, turning to the left, crosses the descending duodenum (Fig. 937). It runs at first transversely to the left, and for the first few inches is comparatively fixed, being united to the front of the descending part of the duodenum and the head of the pancreas either by a very short mesentery or by areolar tissue. Immediately to the left of the head of the pancreas a long mesentery is developed, which allows the colon to hang down in front of the small intestine, at a considerable distance from the posterior abdominal wall. The portion of the colon so suspended is therefore very movable, and consequently its position is very variable, and is influenced by posture and by the condition of the other viscera. Towards

its left extremity the mesentery shortens again, thus bringing the gut towards the tail of the pancreas (Fig. 925), along which it runs upwards into the left hypochondrium, under cover of the stomach, as far as the inferior end of the spleen, where it passes into the left (O.T. splenic) flexure (Fig. 912). Its two ends lie in the right and left hypochondriac regions respectively, whilst its middle portion hangs down into the umbilical, or even the hypogastric region.

Its average *length* is about 19 or 20 inches (47·5 to 50·0 cm.), that is, more than twice the distance, in a direct line, between its two extremities. This great length is accounted for by the curved and somewhat irregular course which the bowel pursues.

Relations.—The greater part of the transverse colon lies behind the greater omentum, which must consequently be turned upwards in order to expose it. *Above*, it is in contact, from right to left (Fig. 928), with the liver and gall-bladder (which also descend in front of the colon), the stomach, and near its left end, with the tail of the pancreas and inferior end of the spleen (Fig. 912). *Anteriorly* are placed the omentum and the anterior abdominal wall; towards its termination the stomach also is anterior. *Posteriorly*, it first lies in contact with the descending duodenum and head of the pancreas; further to the left, where it hangs down, the small intestine is placed below and posteriorly, and it is connected to the posterior abdominal wall by the transverse mesocolon. It is also loosely connected to the stomach by the gastro-colic ligament which is attached to its anterior surface. The transverse mesocolon and the gastro-colic ligament are described with the peritoneum, p. 1155.

The transverse colon is completely covered with peritoneum, with the exception of the first few inches of its posterior surface, which are often, if not usually, uncovered.

The state of the peritoneal covering on the posterior surface of the first part of the transverse colon would seem to depend, in some degree, on the extent to which the liver passes downwards on the right side. With a small, high liver no mesentery is present, and the posterior surface is devoid of peritoneum; on the other hand, when the liver is enlarged in the vertical direction, it pushes the colon downwards before it, and brings the upper line of the peritoneal reflexion from its back, into contact with the lower, thus giving rise to the mesentery. In the fœtus of three or four months every part of the colon is supplied with a long mesentery; subsequently this, as a rule, disappears at the beginning of the transverse colon, but it may be reproduced in the manner stated.

Flexura Coli Sinistra (**Left Flexure of the Colon** (O.T. **Splenic Flexure**)).—The terminal portion of the transverse colon runs upwards (also posteriorly and to the left) until the inferior end or base of the spleen is reached; here it bends sharply, forming the left flexure, and runs down into the descending colon. The flexure is placed deeply in the left hypochondrium, posterior to the stomach, and in contact with the base of the spleen. It lies at a higher level than the right colic flexure, and is connected to the abdominal parietes by the phrenico-colic ligament, which helps to maintain it in this position.

Ligamentum Phrenicocolicum (Fig. 912).—This is a triangular fold of peritoneum, with a free anterior border, which is attached medially to the left flexure and laterally to the diaphragm opposite the ninth to the eleventh rib. (Owing to the fact that the base of the spleen rests upon it, the ligament has also received the older name of sustentaculum lienis.)

The phrenico-colic ligament is formed in the fœtus from the left margin of the greater omentum (Jonnesco).

The peritoneal covering of the left colic flexure is similar to that of the descending colon.

Colon Descendens.—The **descending colon** is much narrower and less obtrusive than the ascending colon: indeed in a large number of cases it is found firmly contracted. It begins in the left hypochondrium at the left flexure, passes down on the left side of the abdomen, and ends in the lumbar region, opposite the crest of the ilium, by passing into the iliac colon. Its course is not quite straight, for it first curves downwards and medially along the lateral border of the left kidney, and then descends almost vertically to the iliac crest (Fig. 937).

Its *length* is usually from 4 to 6 inches (10 to 15 cm.), and its *width*, which is less than that of the ascending colon, about 1½ inches (37 mm.).

Relations.—The descending colon first lies in contact with the lateral border of the left kidney; below that it is placed, like the colon of the opposite side, in the angle

between the psoas and quadratus lumborum muscles. Posteriorly, it rests upon the lower part of the diaphragm above, and on the quadratus lumborum below. Anteriorly (and somewhat laterally also, except when the bowel is distended) are placed numerous coils of small intestine, which hide the colon completely from view, and compress it against the posterior abdominal wall. To its *medial side* lies the inferior part of the kidney above, the psoas major below.

In the great majority of bodies only the front and sides of the descending colon are covered with peritoneum; the posterior surface, being destitute of a serous coat, is connected to the posterior wall of the abdomen by areolar tissue. In a small proportion of cases, on the other hand, the serous coat is complete, and the colon is furnished with a short mesentery.

Up to the fourth or fifth month of fœtal life the descending colon has a complete investment of peritoneum and a long mesentery. After the fifth month the mesentery adheres to, and soon

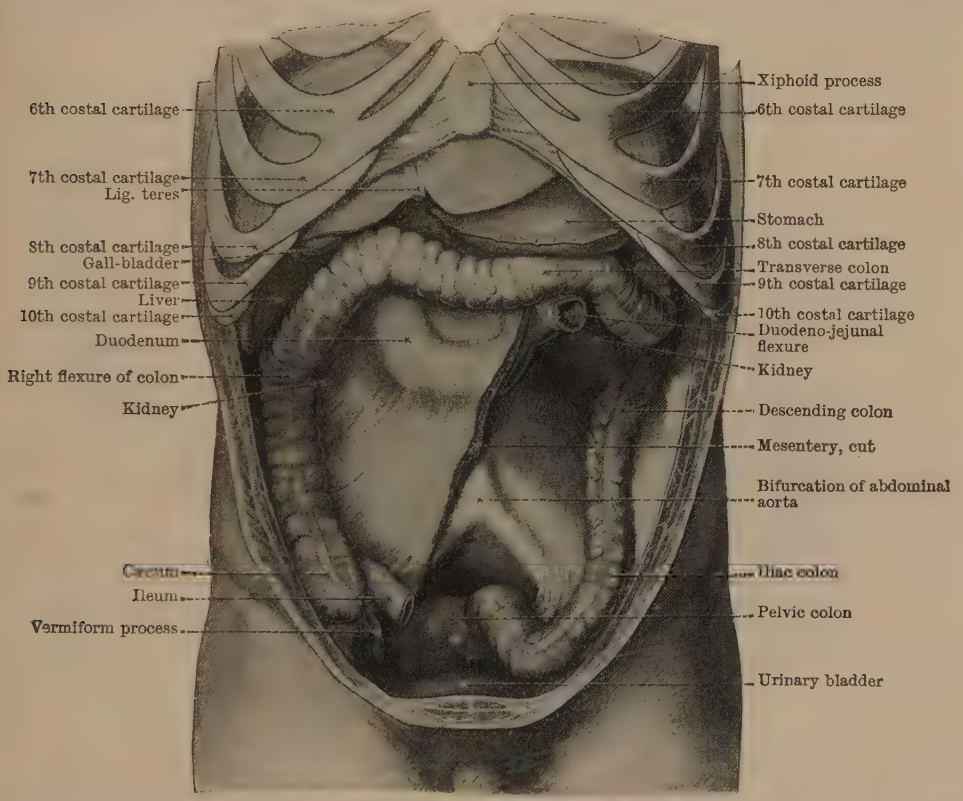

FIG. 937.—THE ABDOMINAL VISCERA AFTER THE REMOVAL OF THE JEJUNUM AND ILEUM (from a photograph of the same body as depicted in Fig. 928). The transverse colon is much more regular than usual.

blends with, the parietal peritoneum on the posterior abdominal wall, and is completely lost as a rule. The persistence of this mesentery, in a greater or less degree, explains the occasional presence of a descending mesocolon in the adult.

Iliac Colon.—This corresponds to the portion of the "sigmoid flexure" which lies in the iliac fossa, and it has no mesentery. It is the direct continuation of the descending colon, with which it agrees in every detail, except as regards its relations. Beginning at the crest of the ilium, it passes downwards and somewhat medially, lying in front of the iliacus muscle. A little way above the inguinal ligament it turns medially over the psoas major, and ends at the medial border of this muscle by dipping into the pelvis and becoming the pelvic colon (Fig. 937). It usually measures about 5 or 6 inches (12·5 to 15 cm.) in length, but it varies considerably in this respect.

Relations.—Posteriorly, it lies upon, and, as a rule, is connected by areolar tissue to, the front of the ilio-psoas muscle. It also crosses the left ureter, the left internal

testicular or ovarian vessels, and the femoral nerve. Anteriorly, it is usually covered by coils of small intestine, which hide it from view; but when distended, or when it occupies a lower position than usual, it comes into direct contact with the anterior abdominal wall. As a rule (90 per cent of bodies—Jonnesco), it is covered with peritoneum only on its sides and anterior surface. Occasionally (10 per cent of cases) it is completely covered, has a short mesentery (1 inch, 2 to 3 cm.), and is slightly movable.

In its course it passes down over the iliac fossa near its middle, generally forming a curve with its concavity directed medially and upwards, and having reached a point 1½ or 2 inches (4 to 5 cm.) above the inguinal ligament, it turns medially across the psoas major towards the pelvic cavity. Occasionally the iliac colon occupies a lower position than this, and runs along the deep surface of the inguinal ligament, immediately behind the anterior abdominal wall.

Pelvic Colon.—The pelvic colon begins at the medial border of the left psoas major muscle, where it is continuous with the iliac colon, and ends at the level of the third sacral vertebra by passing into the rectum. Between those two

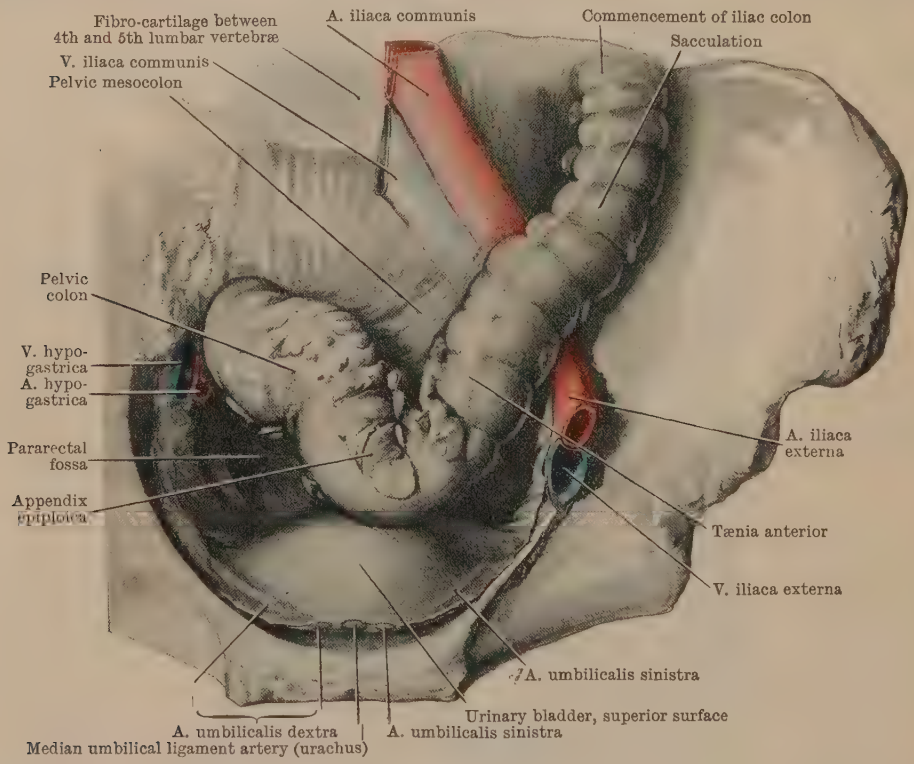

FIG. 938.—THE ILIAC AND PELVIC COLON *IN SITU*.

points it has a well-developed mesentery, and forms a large and variously shaped coil, which usually lies in the cavity of the pelvis (93 per cent).

Whilst the loop of the pelvic colon is very irregular in form, the following may be given as perhaps its most common arrangement. Beginning at the medial margin of the left psoas major, it first plunges over the brim into the pelvis minor, and crosses that cavity from left to right; it next bends backwards and then returns along the posterior wall of the pelvis towards the median plane, where it turns down and passes into the rectum (Figs. 937 and 938).

In *length*, the pelvic colon generally measures about 16 or 17 inches (40 to 42·5 cm.), but it may be as short as 5 inches (12 cm.), or as long as 35 inches (84 cm.).

Relations.—In its passage into the pelvis it crosses the external iliac vessels; in running from left to right across the cavity, it rests on the bladder or uterus, according to the sex; whilst the coils of the small intestine lie above it.

It is completely covered by peritoneum, and is furnished with an extensive mesentery —the pelvic mesocolon—which permits of considerable movement.

In cases where the pelvic colon is unusually long (Fig. 937), in returning from the right side of the pelvis it crosses the median plane, going even as far as the left wall, and then turns back a second time towards the middle of the sacrum, where it joins the rectum at the usual level, thus making an S-shaped curve within the pelvis. On the other hand, when the loop is short (a not infrequent occurrence), all its curves are abridged, and it fails to pass over to the right side, but runs more or less directly backwards after entering the pelvis.

From what has been said it will be seen that the loop of the pelvic colon is subject to numerous and considerable variations, which are dependent chiefly upon its length and that of its mesentery, and also upon the state of emptiness or distension of itself and of the other pelvic viscera. When the intestine is long the loop is more complex; when short, more simple. When the bladder and rectum are distended, or when the pelvic colon itself is much distended, it is unable to find accommodation in the pelvis minor, and consequently it passes up into the abdominal cavity, almost any part of the lower half of which it may occupy. But, as already stated, in the great majority of cases (92 per cent, according to Jonnesco) it is found after death lying entirely within the pelvic cavity.

The **pelvic mesocolon**, which corresponds to both the sigmoid mesocolon and the meso-rectum, is a fan-shaped fold, short at each extremity, and long in its middle portion (Figs. 937 and 938). Its root is attached along an inverted V-shaped line, one limb of which runs up close to the medial border of the left psoas major, as high as the bifurcation of the common iliac artery (or often higher); here it bends at an acute angle, and the second limb descends over the sacral promontory and along the front of the sacrum to the middle of its third piece, where the mesentery ceases, and the pelvic colon passes into the rectum. When the pelvic colon ascends into the abdominal cavity this mesentery is doubled up on itself, the side which was naturally posterior becoming anterior.

Recessus Intersigmoideus.—When the pelvic colon with its mesentery is raised upwards, a small orifice will usually be found beneath the mesentery, corresponding to the apex of the V-shaped attachment of its root to the posterior abdominal wall. This orifice leads into a fossa which is directed upwards, and will often admit the last joint of the little finger. It is known as the *intersigmoid fossa*, and is due to the imperfect blending of the mesentery of the descending colon of the fœtus with the parietal peritoneum. The ureter is found lying behind the apex of this fossa. In the fœtus this mesentery is well developed, and extends from the region of the vertebral column out towards the descending colon. After a time it begins to unite with the underlying parietal peritoneum; but in the region of the intersigmoid fossa the union is rarely perfect, hence the presence of the fossa.

In the **child at birth** only the terminal part of the pelvic colon lies in the pelvis. This is chiefly owing to the small size of the pelvic cavity in the infant. Beginning at the end of the iliac colon, the pelvic colon generally arches upwards and to the right across the abdomen towards the right iliac fossa, where it forms one or two coils, and then passes down over the right side of the pelvic brim into the pelvic cavity. In cases of imperforate anus, it is important to remember, in connexion with the operation for forming an artificial anus, that, whilst the iliac colon is found in the left iliac region, the pelvic colon ("sigmoid flexure") usually lies on the right side, and passes over the right portion of the brim to enter the pelvis.

Structure of the Pelvic Colon.—Only the arrangement of the muscular coat need be referred to. As the tæniæ of the descending colon are followed down, it will be found that the postero-lateral band gradually passes on to the front, and unites with the anterior tænia to form a broad band, which occupies nearly the whole width of this bowel in its lower portion. The postero-medial tænia spreads out in a similar manner on the back; so that in the inferior half of the pelvic colon the longitudinal layer of the muscular coat is complete, with the exception of a narrow part on each side; there the circular fibres come to the surface, and the intestine presents a series of small sacculations. The sacculations disappear, and the longitudinal fibres, although thicker in front and behind, form a continuous layer all round, as the rectum proper is approached.

INTESTINUM RECTUM.

Intestinum Rectum.—The **rectum** is the portion of the large bowel which intervenes between the pelvic colon above and the anal canal—the slit-like passage through which it communicates with the exterior (Fig. 940).

Unlike the portion of the bowel which immediately precedes it, the rectum has but a partial covering of peritoneum, and is entirely destitute of a mesentery; sacculations, too, which are so characteristic of the large intestine, cannot properly be said to be present.

The rectum begins at the termination of the pelvic mesocolon, namely, about the level of the third sacral vertebra, and ends, where the bowel pierces the pelvic floor, opposite the inferior and posterior part of the prostate in the male, or at a point $1\frac{1}{2}$ inches (3·7 cm.) in front of, but at a more inferior level than, the tip of the coccyx in both sexes. It first descends along the front of the sacrum and coccyx, following the curve of these bones; beyond the coccyx, it rests, for about $1\frac{1}{2}$ inches (3·7 cm.), on the posterior part of the pelvic floor, there formed by the union of the

two levatores ani; and finally, having reached the inferior part of the prostate, it bends rather abruptly backwards and downwards, pierces the pelvic floor, and passes into the anal canal (Fig. 939).

Its general direction is downwards, but this varies at its two extremities, being downwards and backwards above, downwards and strongly forwards below.

Curvatures.—The rectum is far from straight, notwithstanding its name, for it is curved in both the antero-posterior and the transverse planes. Viewed *from the side*, it forms a gentle curve, with the convexity posteriorly, which extends from the beginning of the rectum to the back of the prostate, and fits into the hollow of the sacrum and coccyx (**flexura sacralis**). At

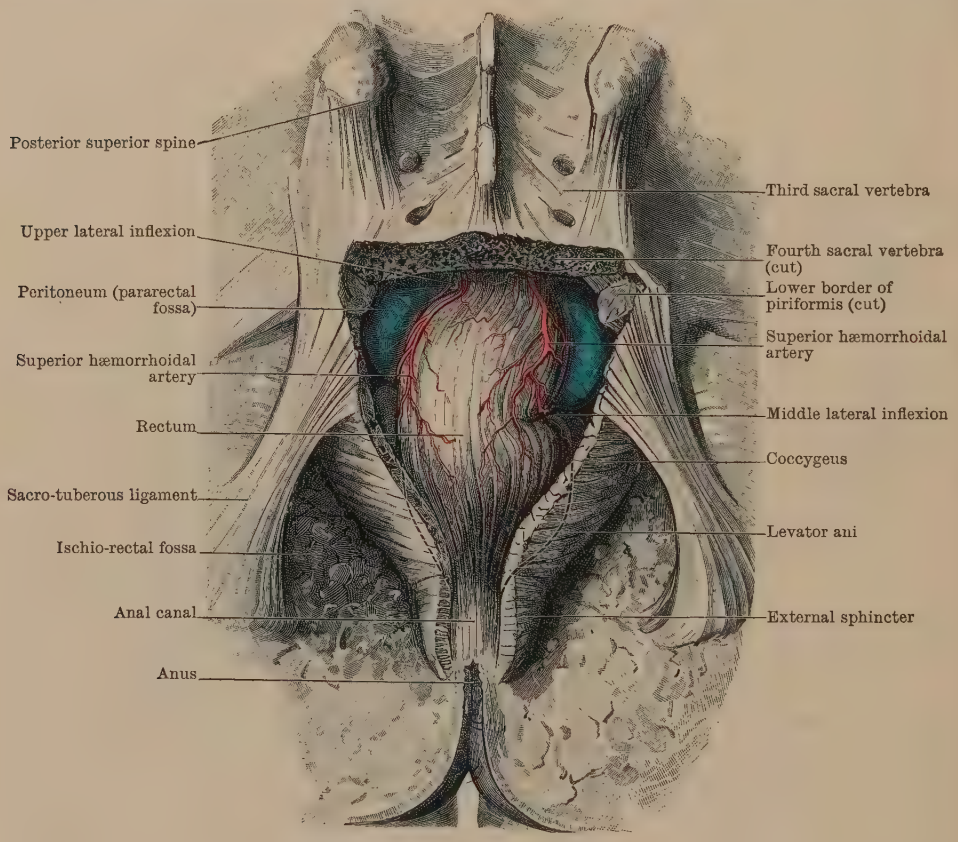

FIG. 939.—THE RECTUM FROM BEHIND.

The sacrum has been sawn across through the 4th sacral vertebra, and its inferior part removed with the coccyx. The posterior portions of the coccygei, levatores ani, and of the external sphincter have been cut away. The "pinching in" of the lower end of the rectum by the medial edges of the levatores ani, resulting in the formation of the flattened anal canal, is suggested in the illustration, which has been made from a formalin-hardened male body, aged 30. The lateral inflexions of the rectum, corresponding to the plicæ transversales recti, are also shown.

the back of the prostate a second curve (**flexura perinealis**) is formed where the rectum joins the anal canal. The convexity of the perineal flexure is directed forwards, whilst its concavity embraces the **ano-coccygeal body**—the mass of muscular and connective tissue which lies between the tip of the coccyx and the anal canal.

When *viewed from the front* the rectum is seen to be regularly folded from side to side in a zigzag fashion, the folding being slightly marked when the rectum is empty, but becoming much more distinct with distension (Figs. 940 and 941). In other words, when viewed from this aspect it presents, in the majority of cases, three more or less distinct lateral flexures or inflexions. Of these the upper and lower have their concavities directed to the left as a rule; the third flexure, which is the best marked, lies between the other two, but on the right side. Not infrequently, however, two are found on the right and one on the left side. The flexures are

marked on the exterior by creases, which appear in the interior as three prominent crescentic shelves (Fig. 940), known as the **plicæ transversales recti**, which help to support the fæcal contents when the rectum is distended.

In *length* the rectum usually measures about 5 or 6 inches (12·5 to 15·0 cm.), but it may be much longer.

Its *diameter* is smallest above, near the junction with the pelvic colon, and is greatest below, near the anal canal, where there is a special enlargement known as the **ampulla recti (rectal ampulla)**. When empty the rectum measures little over

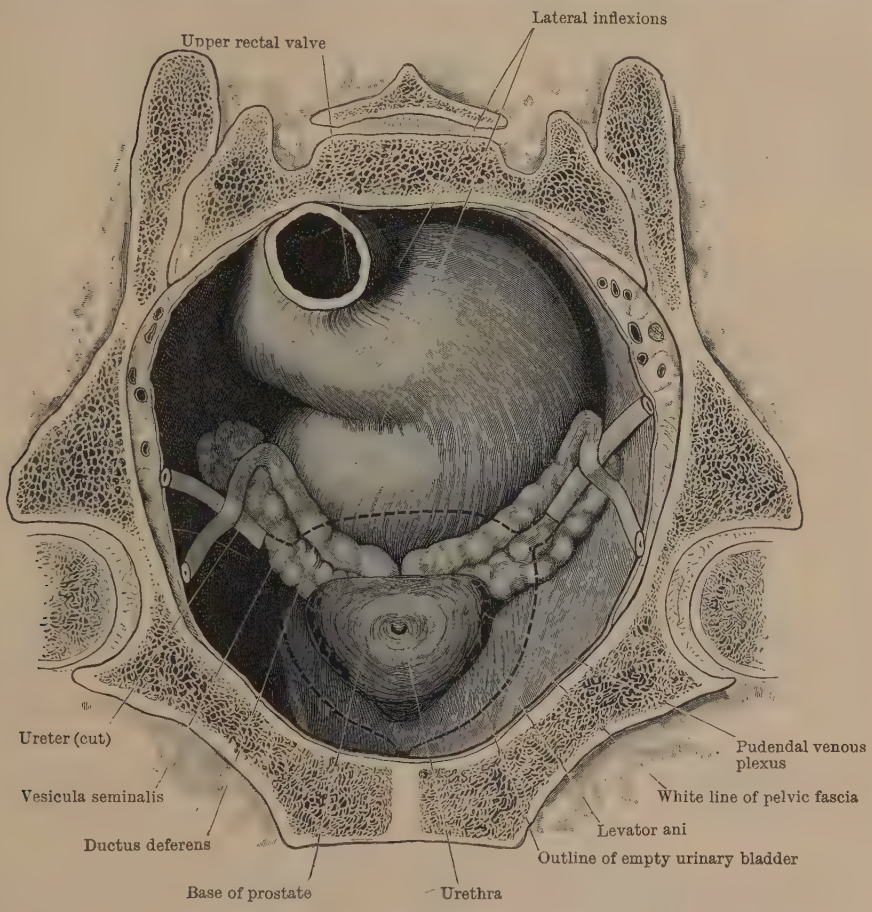

FIG. 940.—DISTENDED RECTUM *IN SITU*.

From a formalin-hardened male body, age 56. The peritoneum and extra-peritoneal tissue were removed, after the pelvis had been sawn along a plane passing through the superior part of the symphysis pubis in front and the lower part of the second sacral vertebra behind. The bladder, which was empty and contracted, has also been removed, but its form is shown by a dotted line. The rectum was very much distended, and almost completely occupied the pararectal fossæ.

an inch (2·5 cm.) in diameter, but in a state of extreme distension it may be as much as 3 inches (7·5 cm.) in width.

This folding is maintained by the arrangement of the longitudinal muscular fibres, the majority of which are accumulated in the form of two wide bands, one on the front, the other on the back of the bowel. These two bands, which are continuous with, and comparable in their functions to, the tæniæ of the colon, are shorter than the other coats of the rectum; hence they give rise, as in the case of the colon, to a folding or sacculation of the tube, which can be effective only at the sides where the longitudinal fibres are fewest, for the front and back are occupied by the thickened longitudinal bands (see p. 1219).

In addition to supporting the fæces, these foldings greatly increase the capacity of the rectum without unduly dilating the tube. When the rectum is empty (Fig. 941) its course is comparatively straight, its lateral flexure being but slightly marked, and its whole calibre very much reduced. In this condition it occupies only a small portion of the posterior division of the pelvic cavity

near the median plane, and at each side, between it and the side wall of the pelvis, is a large fossa of the peritoneum, which, when the bowel is empty, contains a mass of small intestine or pelvic colon (Figs. 938 and 941). When the rectum is distended the lateral flexures become much more marked, and the gut, projecting alternately to each side, passes out beneath the peritoneum, obliterating the pararectal fossæ (Fig. 940), and fills the greater part of the posterior division of the pelvis—a condition which could not be brought about with a straight rectum without an enormous increase in all the diameters of the tube.

At its superior end the rectum, following the curve of the sacrum, slopes downwards and at the same time slightly backwards; its middle portion is practically vertical, but the terminal third or more is directed downwards and forwards at an angle varying from 45° to 60° with the horizontal. The pelvic floor, upon which this latter part rests, forms here a similar angle with the horizontal. The bend which the bowel makes behind the inferior end of the prostate, where the rectum passes into the anal canal, is, as pointed out above, abrupt, and usually approaches a right angle, so that the anal canal itself slopes downwards and backwards at an angle of nearly 45° with the horizontal.

Not uncommonly the abrupt curve, at the junction of the rectum with the anal canal, presents

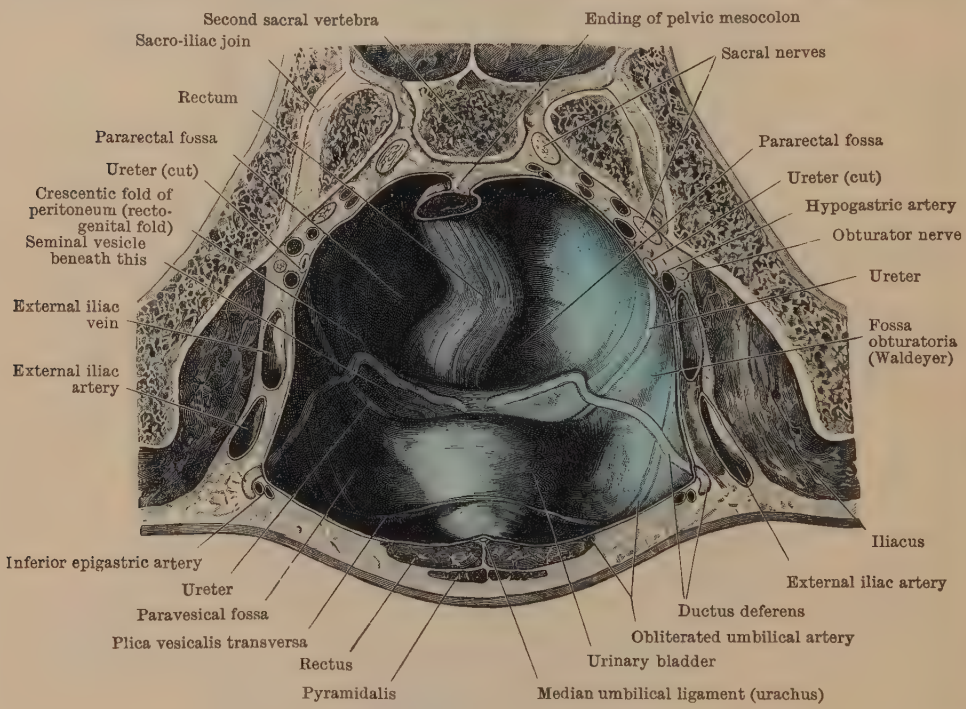

FIG. 941.—THE PERITONEUM OF THE PELVIC CAVITY.

The pelvis of a thin male subject, aged 60, was sawn across obliquely. Owing to the absence of fat the various pelvic organs are visible through the peritoneum, though not quite so distinctly as presented here. The urinary bladder and rectum are both empty and contracted; the paravesical and pararectal fossæ, as a result, are very well marked.

in front a knuckle-like projection (well seen on median section), immediately above the canal. It is most marked in females, and sometimes appears as if the bowel were doubled back upon itself at this point. The floor of the pouch thus formed may dip down in front, even below the level of the upper aperture of the anal canal. This condition is most common in multiparæ, and is evidently due to the relaxed condition of the pelvic structures, and the slight support afforded by the perineal body to this part of the gut in these, and the great capacity and shallowness of the pelvis in the female.

Peritoneal Relations of the Rectum (Figs. 939, 941).—As a rule the superior two-thirds of the rectum has a partial covering of peritoneum—anteriorly and at the sides at first, lower down anteriorly only—whilst the lowest third has no peritoneal investment whatsoever. When the mesocolon ceases at the end of the pelvic colon, its two layers separate and leave the posterior aspect of the rectum destitute of peritoneum. Very soon the membrane quits its sides also, and is then found on the front only; so that the greater part of the rectum lies behind or beneath the pelvic peritoneum, as it were, and is capable of expanding and contracting without being in any way hampered by its partial peritoneal coat.

From the front of the rectum the peritoneum is carried forwards to the base of the bladder in the male, forming the floor of the **excavatio recto-vesicalis** (**recto-vesical** or **recto-genital pouch**, Fig. 941). In the female it passes to the superior part of the posterior wall of the vagina, forming the floor of the **excavatio recto-uterina [cavum Douglasi]** (O.T. **pouch of Douglas**). At each side, in both sexes, it passes from the front of the rectum on to the posterior wall of the pelvis, forming the bottom of a large fossa, seen at the sides of the rectum when that bowel is empty, and known as the **pararectal fossa**. As the rectum becomes distended this fossa is encroached upon by the enlarging bowel, and soon is obliterated.

The level at which the reflexion of the peritoneum takes place from the front of the rectum is of considerable practical importance in connexion with operations in this region. As a general rule that reflexion, that is, the bottom of the recto-vesical pouch, is placed at a distance of 1 inch (2·5 cm.) above the base of the prostate, or about 3 inches above the anus, but the level is subject to considerable variation, being as a rule relatively much higher in well-developed muscular or fatty subjects, whilst in emaciated bodies, owing to the thinness of the structures forming the pelvic floor, it is usually lower.

The bottom of the recto-vesical pouch may reach down in an extreme case to within an inch (2·5 cm.) of the anus, whilst it is not at all rare to find it within 2 inches (5·0 cm.) of that orifice; on the other hand, it may be considerably higher than normal, sometimes being placed at a distance of 4 or 4½ inches (10·0 to 11·2 cm.) from the anus. It should also be added that the level is generally believed to be somewhat raised by distension of the rectum and bladder, and lowered when they are empty.

In the child at birth, the peritoneum extends down to the base of the prostate (Symington), and is thus lower in relation to the bladder; but this may be partly accounted for by the high position of this organ in the child.

As a rule it will be found that 2 inches (5·0 cm.) of the front of the rectum, exclusive of the anal canal, are entirely free from peritoneum, and it is this and the adjacent portion of the bowel which, being free from the restraining influence of the peritoneum, are most distensible, and form the **rectal ampulla**. Including the anal canal, 3½ inches (8·7 cm.) of the rectum, *measured along the front of the tube*, have no serous covering. On the other hand, the back is free from peritoneum for 5 or 6 inches (12·5 to 15·0 cm.)—or sometimes much more—above the anus.

It is also of interest to notice that the connexion of the peritoneum to the rectum varies in its character at different parts: Above and in front it is closely adherent, and can be removed only with the greatest difficulty; at the sides and inferiorly the connexion is much looser. As a result, the peritoneum can be stripped off the rectum in its inferior third or half without much difficulty, whilst in its superior portion this is not the case—an arrangement which admits of the free expansion of the rectal ampulla.

General Relations of the Rectum (Figs. 939 and 940).—*Posteriorly*, the rectum rests on the front of the sacrum and coccyx, and below them upon the posterior part of the pelvic floor—formed by the meeting of the two levatores ani in the ano-coccygeal raphe. When much distended it also comes into relation, on each side, with the lower part of the piriformis and the sacral plexus, but is separated from them by a very considerable amount of connective tissue, arranged (apparently in several layers) around the tube. In this tissue the two chief branches of the superior hæmorrhoidal vessels lie behind the superior part of the bowel, but lower down they are placed in relation to its sides.

At its sides above are the pararectal fossæ and their contents (pelvic colon, or ileum); below the pararectal fossæ the rectum is in contact with the coccygei and levatores ani muscles, which run backwards to the coccyx on each side of the bowel. The branches of the superior hæmorrhoidal vessels are also found running down on its muscular coat, as far as the middle of the rectum, where they pierce the wall of the bowel.

Anteriorly, in the male the rectum is separated from the bladder, to within an inch of the prostate, by the recto-vesical pouch of peritoneum, which usually contains some coils of small intestine. Below the reflexion of the peritoneum the front of the bowel is in contact with the posterior aspect of the bladder, the deferent ducts, vesiculæ seminales, and the posterior aspect of the prostate gland (Fig. 940), from all of which it is separated by the recto-vesical layer of the pelvic fascia.

The lower portions of the rectum and bladder in the male are separated by the recto-vesical fascia only, over a narrow triangular area which measures about an inch (2·5 cm.) in vertical height. The base of the triangle corresponds to the reflexion of the peritoneum from one organ to the other, and the apex to the union of the sides formed by the deferent ducts, which lie very close to one another except above, near the base of the

triangle, where they diverge rather abruptly (Fig. 940). Through the triangle the operation of tapping the bladder from the rectum used to be performed.

The vesiculæ seminales, unless when of a small size, slope laterally and posteriorly round the front and sides of the distended rectum (Fig. 940), which they thus embrace, as it were, within their grasp.

The ureters, as they run medially towards the base of the bladder, lie close in front of the deferent ducts, and are not far separated from the distended rectum (see Fig. 940).

In the female the rectum is separated from the posterior surface of the uterus and the upper end of the vagina by the recto-uterine pouch and the intestine which it usually contains. Below the peritoneal reflexion it is in direct contact with the posterior vaginal wall, to which it is connected loosely above, but more closely below.

The portion of the rectum below the level of the peritoneal reflexion is surrounded by the **rectal fascia**, a layer of connective tissue which is derived from the visceral layer of the pelvic fascia.

In the **child** the rectum, or at least its superior part, is relatively larger, and it pursues a much straighter course than in the adult. As pointed out above, its peritoneal covering likewise descends lower at birth, and reaches as far as the base of the prostate.

PARS ANALIS RECTI—ANAL CANAL.

Pars Analis Recti.—In order to reach the exterior, it is necessary for the lower end of the bowel to pierce the floor of the pelvis. This it does by passing through the narrow interval left between the medial borders of the levatores ani muscles (Fig. 939). As it passes between them, the two muscles pinch in the tube, and by the apposition of its side walls obliterate its cavity, reducing it to a mere slit-like passage. This passage, through which the rectum communicates with the exterior, is the "anal canal" (Symington).

The term **pars analis recti** refers, strictly, to the lower half only of this canal, which is lined by squamous epithelium, and shows the columnæ rectales.

Formerly this terminal portion of the tube was described as the "third part of the rectum," and, like the rest of that bowel, it was supposed to form a reservoir for the retention of the fæces. It is probable that only when the rectum is distended is the superior part of the anal canal occupied by the wedge-shaped lower end of the contained fæcal mass.

The anal canal *begins* where the rectum proper terminates, namely, at the level of the levatores ani muscles, opposite the inferior part of the prostate. Below, the anal canal *ends* at the anus, or anal orifice, by opening on the exterior.

Its *length* is usually from 1 to 1½ inches (2·5 to 3·7 cm.), being greater when the bowel is empty, and less when it is distended. Its antero-posterior diameter when closed varies between ½ and ¾ inch (12 to 19 mm.).

The *direction* of the anal canal, as already pointed out, is downwards and posteriorly, often forming an angle of nearly 45° with the horizontal, although it is usually somewhat nearer to the vertical.

Relations.—It is *surrounded* by both the external and internal sphincters, and above also by the borders of the levatores ani, these muscles forming a muscular cylinder around it (Fig. 943). *On each side* is situated the ischio-rectal fossa with its contained fat, which allows of the distension of the canal during the passage of fæces. *Posteriorly* is placed a mass of mixed connective and muscular tissue, known as the **ano-coccygeal body** (Symington), which intervenes between it and the coccyx. Finally, *anteriorly*, it lies close behind the bulb of the urethra and the base of the urogenital diaphragm in the male, and a sound in the urethra can be easily felt by the finger introduced into the anal canal, particularly in thin bodies. In the female it is separated from the vagina by the wedge-shaped mass of fatty and muscular tissue known as the "perineal body."

Structure of the Rectum and Anal Canal.—The wall of the rectum is made up of four coats, viz.: 1. The **outer coat**, formed in part by peritoneum (already described), and, where the peritoneum is absent, of connective tissue which can be dissected off in several layers. In this connective tissue the hæmorrhoidal vessels run until they pierce the wall of the tube. In it also, at the back and sides of the rectum, are found embedded a number of rectal lymph glands.

2. The **tunica muscularis**, which is much thicker than in any other portion of the intestine, is composed of two stout layers of unstriped muscle—an outer longitudinal and an inner circular—like that of the intestine generally. The *longitudinal fibres*, although present all round, are

accumulated chiefly on the front and back of the tube (see p. 1215), where they form two broad bands; at the sides they are reduced to a thin layer, the deepest fibres of which are folded in and take part in the formation of the rectal valves.

Where the rectum pierces the floor of the pelvis, the outer layer of longitudinal fibres is united to the deeper portion of the levator ani, partly by tendinous fibres and partly by an interchange of muscular fibres, between the levatores and the muscular coat of the rectum. Below, the longitudinal fibres pass between the external and internal sphincter muscles, or through the latter to join the skin around the anus.

In sagittal sections of the pelvis near the median plane there can generally be seen a distinct band of red, longitudinally arranged, muscular fibres, which descends on each side from the front of the coccyx to blend with the longitudinal fibres on the back of the rectum. This band is the **rectococcygeus muscle.** It is composed of striped fibres above, but becomes unstriped below.

Some unstriped muscular fibres which are found descending in the subcutaneous tissue of the lower part of the anal canal, to join the skin around the anus, have been described by Ellis as the **corrugator cutis ani.** According to Roux, they are some of the longitudinal fibres of the rectum which have passed through the internal sphincter to the submucous tissue, and then descended to the skin. The front of the rectum at the perineal flexure is, in the male, connected to the back of the membranous urethra by a band of muscle, termed the **recto-urethralis.**

The *circular fibres* form, along the whole length of the tube, a continuous layer, which is doubled inwards to assist in the formation of each rectal valve, and is thickened below to form the **internal sphincter** of the anus. The **sphincter ani internus,** as just pointed out, is formed by a great, and rather sudden, increase of the circular muscular fibres, which begins at the superior end of the anal canal. It surrounds the canal for about an inch (2·5 to 3·0 cm.), and terminates at its junction with the skin.

3. The **tela submucosa** is composed of loose areolar tissue, which allows of a free movement of the mucous layer on the muscular coat, and which also admits, under certain abnormal conditions, of a prolapse of the mucous membrane through the anal orifice. The hæmorrhoidal plexus of veins is contained in this layer.

4. The **tunica mucosa** must be considered separately in the rectum and pars analis recti. That of the rectum is redder in colour than the mucous membrane of the colon, as a result of its greater vascularity. It is also thicker, and owing to the looseness of the underlying submucosa, is thrown into numerous irregular rugæ when the rectum is empty; these disappear when the bowel is distended, and there then become evident three (sometimes more, sometimes less) crescentic folds, which are much less noticeable in the empty state, and which have been already referred to as the plicæ transversales recti. Lymph nodules and intestinal glands are present; but these latter are not so numerous as in the colon, although their calibre is greater.

The *mucous membrane of the pars analis recti* presents a number of vertical ridges known as the *columnæ rectales* (Morgagnii); between the lower ends of these are found a series of small semilunar folds which connect the lower ends of these columns together and are called the *anal valves* (Fig. 942). Above the level of the anal valves the canal is lined by a modified mucous membrane resembling that of the rectum; the portion below the valves (*i.e.* the lower 12 to 16 mm. of the canal) is covered by modified skin, continuous with that around the anus.

The term *annulus hæmorrhoidalis* is applied to the segment enclosed by the sphincter externus muscle. It extends from the region of the rectal sinuses to the anal orifice, and in its wall is found the large venous plexus termed the *plexus hæmorrhoidalis.*

The mucous membrane of the rectum presents a characteristic punctated appearance, which is due to the presence of a considerable number of rounded depressions, such as might be made by firmly pressing a finely pointed pencil against the membrane. These *rectal pits* are tubular in form, and have an accumulation of lymph tissue at the bottom of each, the whole appearance being such as might be produced if a small solitary nodule were drawn down from the surface into the intestinal wall.

Plicæ Transversales Recti (Houston).—These are crescentic shelf-like folds which project into the cavity of the rectum (Fig. 942). They are composed of an infolding of the mucous, submucous, and greater part of the circular muscular coats, and their form is preserved by the relative shortness of the anterior and posterior bands of longitudinal muscular fibres. They are produced, as pointed out above, by the projection, into the interior of the bowel, of the creases on the exterior which result from the lateral inflexions of the rectum. In the majority of cases three are present (there may be four, five, or, it is said, even more), but often the lowest of the three is small or absent; or all the valves may be ill-developed and indistinct. They are most evident in a distended rectum which has been hardened *in situ*; they can also be seen during life, *per anum,* with the aid of a rectal speculum.

As a rule two valves are found on the left and one on the right side; this latter is generally the largest, and is situated a little above the level of the peritoneal reflexion, viz., 3 or 3½ inches (7·5 to 8·7 cm.) above the anus; the other two valves are found about 1 to 1½ inches (2·5 to 3·7 cm.) higher up and lower down respectively. The valves are distinctly marked in the fœtus, and seem to constitute an essential part of the human

rectum, their use being to support the contents of the rectum, which they break up into segments, each supported by a valve. They are said to interfere sometimes with the introduction of an enema tube.

Columnæ Rectales [Morgagnii].—The mucous membrane of the pars analis recti, or lower portion of the anal canal, presents a number (5 to 10) of *permanent* vertical folds, separated by grooves, and known as the **columnæ rectales** (O.T. **columns of Morgagni**) (Fig. 942). They are usually $\frac{1}{3}$ to $\frac{1}{2}$ inch (8 to 12 mm.) in length, $\frac{1}{8}$ to $\frac{1}{4}$ inch (3 to 6 mm.) in width, and they extend down to within $\frac{1}{2}$ or $\frac{2}{3}$ inch (12 to 20 mm.) of the anal aperture. They are formed by infoldings of the mucous membrane, containing in their interior some bundles of longitudinal muscle and also, as a rule, an artery and a vein.

Very often the contained vein presents an enlargement, or a knob-like tortuous plexus in the lower part of the column; below this the plexus is continued down *external* to the mucous membrane of the lower zone of the anal canal into the anal veins. This portion has accordingly been described as the hæmorrhoidal zone of the anal canal. Sometimes the columns are very indistinct; occasionally no trace of them can be found, although in the fœtus they are usually well marked.

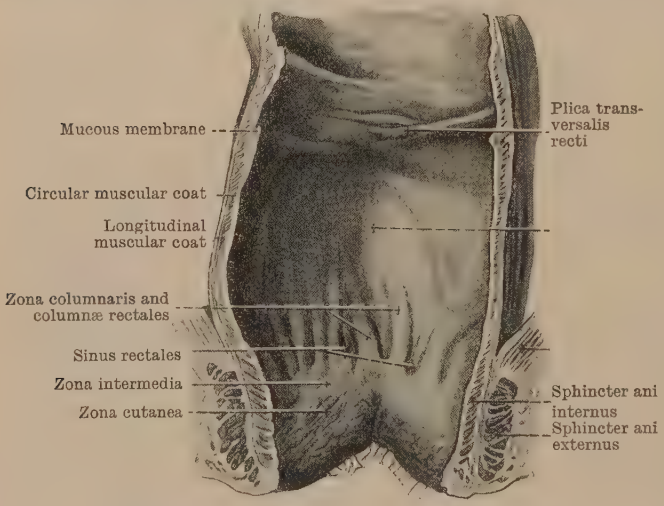

FIG. 942.—INTERIOR OF THE ANAL CANAL.

Anal Valves.—If a probe is passed downwards along the groove which separates two adjacent columnæ rectales (Fig. 942), its point will usually catch in a small crescentic fold which joins the lower ends of the two columns. These little folds, which resemble in miniature the segments of the semilunar valves of the heart, are the anal valves. They project inwards and upwards, and behind each is found a little pocket-like sinus (**sinus rectalis**).

Anus or Anal Orifice.—At the inferior aperture of the anal canal, the modified skin of its lower zone passes into the ordinary skin.

The junction of the parts derived from endoderm and ectoderm respectively (see Development of Cloaca, p. 53) cannot be readily determined. The skin round the margin of the anus possesses hair follicles and glands (circum-anal glands) and forms a zone, termed the cutaneous zone.

Within this zone is a second one, zona intermedia, not sharply marked off, but separated by the ano-cutaneous line, which is taken to be the line beyond which hairs occur. It is lined by a stratified squamous epithelium.

The third zone—the zona columnaris—corresponds to the region of the rectal columns, and is lined by columnar epithelium.

It is clearly marked off from the intermediate zone by a line which is abrupt, and follows the level of the anal valves, and crosses the bases of the columns between the valves.

This sinuous line is the "ano-cutaneous line" of Hermann or the "white line" of Hilton.

Action of the Sphincters.—In connexion with the anal canal are found three muscles—namely, the paired levatores ani, the external sphincter, and the internal sphincter—the action of which may be briefly referred to here.

Levator Ani.—The fibres of the levator which arise from the pubis (pubo-coccygeus or sphincter recti portion) pass backwards on each side of the beginning of the anal canal, and, in great part, meet behind the passage. These two muscular bands—which are but a little distance

apart at their origin, and are actually united behind the bowel—are closely approximated during the contraction of the muscles, like the limbs of a clamp, and, pressing on the sides of the anal canal, they assist in closing the upper part of that passage, whilst at the same time drawing it slightly towards the pubes. There is little doubt that the levator ani in this way acts as one of the chief sphincters of the bowel; and it should be noticed that it is placed where its action would be most effective, namely, opposite the point at which the rectum is narrowed or "pinched in" to form the anal canal. In addition to its sphincter action the muscle supports the expanded bowel immediately above the anal canal, and in this way sustains the weight of the fæces when the rectum is distended. It is probably relaxed during defæcation, except perhaps at the completion of the act. The muscle is under the control of the will.

The **m. sphincter ani externus** forms a muscular cylinder around the inferior two-thirds of the anal canal, with (except in the case of some of its inner fibres) an anterior and a posterior attachment. When the muscle contracts, its fibres are tightly stretched between its two attachments, and the space between them is reduced to a narrow antero-posterior slit. By this action the anal canal is flattened from side to side and closed, so that, whilst the levator ani is the sphincter of the upper aperture of the anal canal, the external sphincter closes its inferior and greater part.

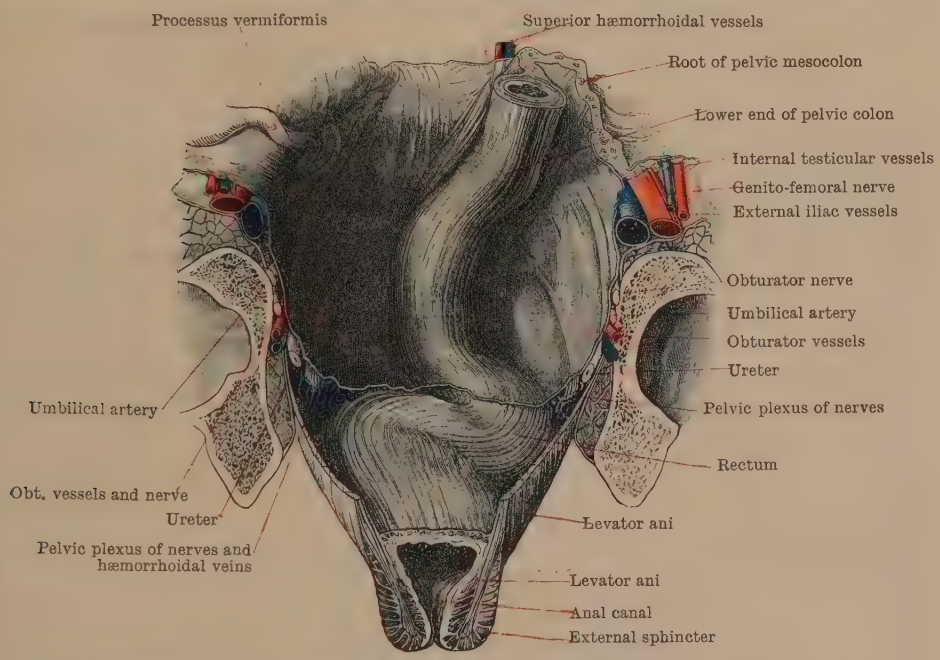

FIG. 943.—DISSECTION OF THE RECTUM FROM THE FRONT IN A SPECIMEN HARDENED BY FORMALIN INJECTION.

The front wall of the pelvis has been removed, and the bladder, prostate, and seminal vesicles taken away.

It is under the control of the will, but under ordinary circumstances it is in a state of tonic contraction.

The **m. sphincter ani internus** is merely a thickening of the circular muscular coat at the inferior end of the bowel. It is continuous with the circular fibres of the gut, not only in structure, but probably also in action, its chief use being to empty the anal canal completely, after the passage of each fæcal mass. Owing to the fact that the canal is an antero-posterior slit, not a circular orifice, and that the internal sphincter forms a muscular ring around it, acting alone, it is scarcely competent to keep the sides of the canal in apposition, and probably it acts rather as a detrusor than a true sphincter of the anal passage.

Vessels.—The rectum and anal canal receive their blood supply from three chief sources, namely, the three hæmorrhoidal arteries; to these another less important, though constant, source may be added—the middle sacral artery.

1. The **superior hæmorrhoidal artery**, the principal artery of the rectum, is the prolongation of the inferior mesenteric. At first it descends in the root of the pelvic mesocolon until the rectum is reached. Here it divides into two chief branches which run downwards and forwards around the sides of the rectum—the right, usually the larger, lying more posteriorly, the left more anteriorly, and the two, as it were, embracing the bowel between them. From these two arteries come off secondary branches (about five to eight in all), which pierce the muscular coat about the middle of the rectum, and then descend in the submucosa as a series of longitudinally running "terminal branches" as far as the anal valves, above the level of which one is usually found beneath each of the rectal columns. These terminal branches give off numerous twigs in their course, which form a hæmorrhoidal plexus in the submucosa by

anastomosing with one another, and also with branches of the middle, and, in the inferior part of the bowel, of the inferior hæmorrhoidal artery.

2. The **middle hæmorrhoidal arteries**, two in number—one on each side—are usually branches of the hypogastric or of the internal pudendal; they run on the wall of the inferior part of the rectum, and each breaks up into four or five small branches, some of which supply the muscular wall of the inferior part of the rectum, whilst the others pierce the muscular coat near the superior end of the anal canal, and join in the submucosa with the plexus formed by the superior hæmorrhoidal artery already described.

3. The **inferior hæmorrhoidal arteries**, generally two or three in number on each side, arise at variable levels from the internal pudendal. They are distributed to the levatores ani and the sphincters. Other branches pierce the sphincters and break up in the submucosa into a close network which supplies the inferior part of the anal canal, and communicates above with the plexus formed by the superior and middle hæmorrhoidal arteries. The inferior hæmorrhoidal artery is distributed chiefly on the posterior, and the middle hæmorrhoidal chiefly on the anterior aspect of the lower part of the bowel.

4. One or more small branches of the **middle sacral artery** reach the posterior surface of the rectum, where they are distributed chiefly, if not solely, to the muscular coat.

Anastomosis of the Hæmorrhoidal Arteries.—The superior and middle hæmorrhoidal arteries anastomose freely in the hæmorrhoidal plexus of the submucosa, and also by a few large branches on the exterior of the bowel: some perforating branches of the middle sacral and inferior hæmorrhoidal arteries also join the plexus in the submucous layer at the lower part of the rectum. In addition, small branches of these several arteries unite with one another in the muscular coat. It should be remarked that the superior hæmorrhoidal artery supplies both the muscular and mucous coats in the superior part of the rectum, but the muscular coats in the inferior part are supplied by the middle and inferior hæmorrhoidal vessels only.

Veins of the Rectum and Anus.—These form two chief plexuses of large vessels devoid of valves, namely, the internal hæmorrhoidal plexus situated in the submucous coat, and the external hæmorrhoidal plexus in the outer coat. The **internal hæmorrhoidal plexus** takes origin near the margin of the anus in a number of small (anal) veins, which are radially disposed beneath the skin of the anus, and communicate below with the rootlets of the inferior hæmorrhoidal vein over the external sphincter. These **anal veins**, traced upwards, join together, and are joined by others from the surrounding parts to form larger and often tortuous vessels, which ascend in the columnæ rectales, where they frequently present ampullary enlargements, varying in size up to that of a small pea, which are said to be the starting-points of hæmorrhoids. Passing upwards, the veins are known as the "terminal veins"; they communicate freely with one another, forming the plexus, and unite into still larger vessels, which pierce the muscular coat about the middle of the rectum, and join to form the superior hæmorrhoidal vein.

From the inferior part of the internal hæmorrhoidal plexus numerous vessels pass through the external sphincter to join a venous network on the outer surface of that muscle, from which the **inferior hæmorrhoidal veins** arise. This network, as pointed out above, also communicates with the internal hæmorrhoidal plexus, through the anal veins which descend from the latter beneath the skin of the anal canal, to the exterior of the sphincter.

The various veins which pass out through the walls of the rectum unite freely on its exterior to form a rich venous plexus **(external hæmorrhoidal plexus)**, through which the three hæmorrhoidal vessels are brought into free communication with one another. Passing off from this plexus, the **superior hæmorrhoidal** joins the left colic vein and forms with it the inferior mesenteric vein, which opens into the splenic; the middle hæmorrhoidal joins the hypogastric, from which the blood passes through the common iliac to the vena cava inferior; and the inferior hæmorrhoidal joins the internal pudendal, a tributary of the hypogastric vein. Thus, on the rectum, a free anastomosis is established between the veins of the portal and systemic circulations.

Lymph Vessels.—Most of the lymph vessels of the rectum pass to the lymphoglandulæ sacrales, of which some lie close to the muscular coat on the side of the rectum along the superior hæmorrhoidal vessels, while others, four or five in number, and of a larger size, lie in front of the promontory of the sacrum, between the layers of the pelvic mesocolon. The glands of opposite sides are connected with one another by the middle sacral plexus and with the hypogastric and mesocolic lymph glands. The efferent vessels from these pass to the lumbar glands. Some of those from the lower part of the anal canal join the cutaneous lymph vessels round the anus, and pass with them to the inguinal and subinguinal glands. A few of the lymph vessels from the lower portion of the rectum are said (by Quenu) to join the hypogastric glands.

Nerves.—The nerves of the rectum come partly from the sympathetic and partly from the cerebro-spinal system. The sympathetic fibres are derived from the inferior mesenteric plexus, through the superior hæmorrhoidal nerve and the corresponding plexus, and from the upper and lower divisions of the hypogastric plexus, the former accompanying the superior hæmorrhoidal, the latter the middle hæmorrhoidal vessels, to the rectum. The cerebro-spinal fibres arise from the second, third, and fourth sacral nerves soon after these leave the sacral foramina (and constitute the "pelvic splanchnics" of Gaskell). They run forward in the pelvic connective tissue, and joining the pelvic plexuses, reach the side of the rectum. Fibres of the inferior hæmorrhoidal branches of the pudendal nerve (third and fourth sacral) are also distributed to the lower part of the anal canal as well as to the external sphincter.

It has been shown by experiments on animals, that the cerebro-spinal nerves (from the

second, third, and fourth sacral) convey motor impulses to the longitudinal fibres, but inhibitory impulses to the circular muscular fibres. In like manner the branches from the sympathetic convey motor fibres (derived from some of the lumbar rami communicantes) to the circular muscle, and inhibitory fibres to the longitudinal muscle of the rectum.

The reflex centre which governs the action of the sphincters and the muscular fibres of the rectum ("defæcation centre") is situated in the lumbar region of the spinal medulla, and appears to be capable of carrying out the whole act of defæcation even when separated from the brain.

Variations.—The best known anomalies found in connexion with the rectum are those classed under the term **imperforate anus** or **atresia ani.** The atresia may be simply due to a partial or complete persistence of the anal membrane (see p. 46), which separates the proctodæum from the hind-gut in the embryo (atresia ani simplex); or the hind-gut may be deficient in its lower part, when there is a considerable interval between the proctodæum and the gut (defectus recti partialis, vel totalis); or the rectum may open into the vagina, the uterus, the bladder, or the ureters, when usually no anus is evident; or finally the cloaca may persist. Other forms are also described, but the foregoing are those most commonly found.

For the **development** of the rectum and anus, see pp. 53 and 55.

PERITONEUM.

As already explained, the peritoneum is the serous membrane which, on the one hand, lines the abdominal cavity, and on the other forms a more or less complete covering for the contained viscera. The portion which lines the walls of the cavity is known as the **parietal peritoneum**; that which clothes the viscera is called the **visceral peritoneum.** The membrane is connected to both walls and viscera by a layer of areolar tissue—**tela subserosa**, the extra or subperitoneal connective tissue.

The peritoneal cavity is described as consisting of two portions—the general peritoneal or **great sac** and the **bursa omentalis.** The great sac is opened when the anterior abdominal wall is removed or incised, and the peritoneum which encloses it lines the greater portion of the wall of the abdominal cavity, and invests most of the abdominal viscera; the omental bursa lies chiefly on the posterior aspect of the stomach, and is much smaller. It must be clearly understood that these two sacs are not two separate cavities, but simply subdivisions of one great cavity; for the omental bursa is merely a recess of the greater sac, from which it has become partly shut off largely by changes that take place in the position of the adjacent viscera during their development. If the general peritoneal cavity is compared to a bag, the bursa omentalis might be represented as a pocket lying behind, and opening into it by a narrow orifice—the foramen epiploicum [Winslow].

The **general peritoneal sac** is placed between the parietes anteriorly and the abdominal viscera posteriorly. It is composed of two layers: an anterior, which lines the anterior abdominal wall; and a posterior, which mainly covers the viscera; but this posterior layer is carried forwards by the viscera, so that the two layers come in contact, and the cavity of the sac is practically obliterated.

The **anterior layer of the peritoneum** covers the anterior abdominal wall completely, from the diaphragm above to the pelvis below. Over the greater part of its extent the connexion of the serous membrane to the wall is by a small amount of fatty extra-peritoneal connective tissue; but below, near the pubic region, the fat is more abundant, and the connexion between the two becomes much looser. This is to allow of the movement of the peritoneum which takes place there during distension of the bladder. As the bladder enlarges it passes up in the extra-peritoneal tissue of the lower part of the anterior abdominal wall, off which it raises the peritoneum, so that, in the fully distended condition, the anterior surface of the bladder is in contact with this wall, without the interposition of peritoneum, for a distance of two inches (5·0 cm., or occasionally more) above the pubes (Fig. 944).

Running up in the fatty subserous tissue are found five cord-like structures, one placed in the median plane, and two at each side. These are (*a*) the **lig. umbilicale medium** (O.T. **urachus**)—the remains of the allantois of the fœtus—which in the adult is a slender fibrous band connected to the umbilicus above, and to the apex of the bladder below, where it usually becomes much stouter. Lateral to

the urachus, and some distance from it (Fig. 941), will be found, in the same fatty tissue, (*b*) two stouter fibrous cords, the obliterated **umbilical arteries** (O.T. **obliterated hypogastric arteries**), forming the **plica umbilicalis lateralis dextra** and **sinistra**. Traced upwards, these also become more slender, and approach the urachus, along with which they are connected to the umbilicus. Below, they grow thicker, and can be followed backwards along the side wall of the pelvis to the hypogastric arteries, which they join. (*c*) More laterally still, the **inferior epigastric arteries** are seen running upwards and medially from the external iliac trunk on each side.

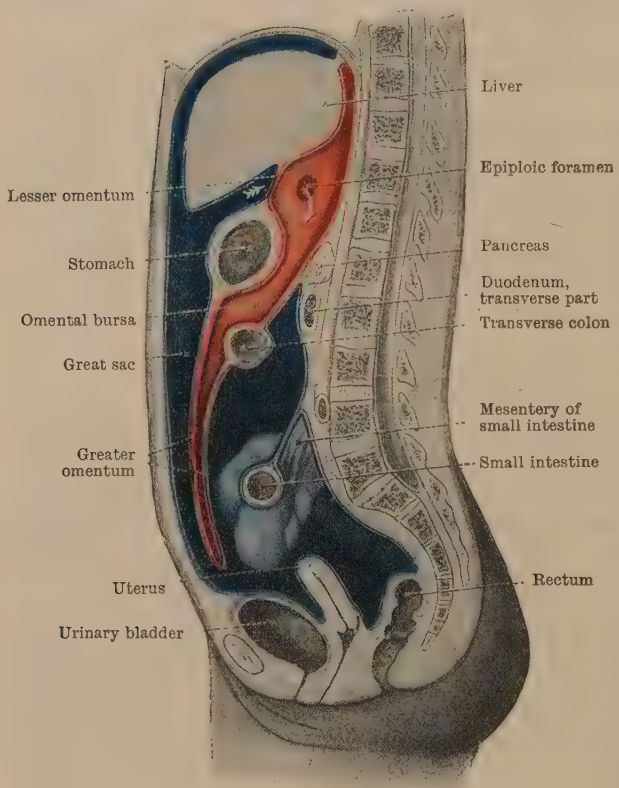

FIG. 944.—DIAGRAMMATIC MEDIAN SECTION OF FEMALE BODY, to show the abdomino-pelvic cavity and the peritoneum on vertical tracing. The great sac of the peritoneum is blue and is represented as being much larger than in nature; the bursa omentalis is coloured red; the peritoneum in section is shown as a white line: and a white arrow is passed through the epiploic foramen from the great sac into the bursa omentalis.

When the anterior abdominal wall is examined from behind, it will be seen that these five structures, which lie on the front of the peritoneum, carry that membrane inwards towards the abdominal cavity in the form of five more or less distinct ridges, known as the **plica umbilicalis media, plicæ umbilicales laterales**, and **plicæ epigastricæ**, respectively. In relation to these are found on each side three peritoneal fossæ, known as the **foveæ inguinales** (O.T. **inguinal pouches or fossæ**).

The **fovea inguinalis lateralis** lies lateral to the inferior epigastric artery, and corresponds to the position of the abdominal inguinal ring. At its bottom is often found a dimple-like depression of the peritoneum, indicating the point from which the processus vaginalis passed down, in connexion with the descent of the testis. The **fovea inguinalis medialis** is situated between the inferior epigastric and the obliterated umbilical arteries; whilst the **fovea supravesicalis** lies to the medial side of the obliterated umbilical artery, namely, between it and the urachus.

Between the inferior epigastric artery laterally, the margin of the rectus abdominis muscle medially, and the inguinal ligament below, there is a small triangular region, called Hesselbach's triangle. The obliterated umbilical artery, in passing upwards, crosses this triangle, dividing it into a lateral and a medial part. The middle inguinal fossa corresponds to the lateral division of the triangle, and the medial fossa to its medial division.

Still another fossa of the peritoneum is seen in this region, just beneath the medial part of the inguinal ligament, corresponding to the position of the femoral ring, and consequently known as the **fovea femoralis**. It may be added that the ductus deferens crosses the lateral part of the fovea femoralis, and the obliterated umbilical artery its medial part. The significance of those fossæ is referred to in connexion with the applied anatomy of the inguinal and femoral regions.

Near the median plane, above the umbilicus, the peritoneum is carried back from the anterior abdominal wall and diaphragm to the parietal surface of the liver in the form of a crescentic fold, the **falciform ligament** of the liver (described with the liver), which connects the liver to the abdominal wall. This fold lies somewhat to the right of the median plane, and extends almost as low down as the umbilicus. It consists of two layers of peritoneum, between which, in the lower border of the fold, runs the round ligament of the liver—the remains of the left umbilical vein of the fœtus.

Posterior Wall of the General Peritoneal Cavity.—The peritoneum clothing the anterior abdominal wall is continued on to the inferior surface of the diaphragm. Thence it is reflected on to the superior surface of the liver, turns round its anterior border, and is continued back on the inferior surface as far as the attachment of the lesser omentum, where it quits the liver and passes down, as the anterior layer of the lesser omentum, to the stomach and the duodenum.

The line of reflexion of the peritoneum from diaphragm to liver is interrupted near the median plane by the falciform ligament. The portion lying to the right of this fold forms the superior layer of the coronary ligament; that to the left of it, the superior layer of the left triangular ligament of the liver.

The extent to which the peritoneum passes uninterruptedly back on the inferior surface of the liver varies according as it is traced at the right, the left, or the middle portion of the liver. It clothes the right portion as far back as the inferior edge of the uncovered area of the liver, where it is reflected on to the posterior wall of the abdomen and the superior extremity of the right kidney (constituting the hepato-renal ligament), as the inferior layer of the coronary ligament. On the left portion it is continued back as far as the posterior border of the left lobe—or even a little way on to its superior surface—whence it passes to the diaphragm as the inferior layer of the left triangular ligament. The middle region of the under surface it clothes only as far as the porta hepatis and the fossa of the ductus venosus; from those the peritoneum is carried down as the anterior layer of the lesser omentum.

The peritoneum, on the inferior surface of the diaphragm to the left of the liver, is continued down on the posterior abdominal wall, behind the fundus of the stomach and the spleen, until the left kidney is reached. It covers the superior and lateral part of the kidney, and is then carried forwards as the **lieno-renal ligament** to the spleen, around which it passes —clothing its renal, phrenic, and gastric surfaces—as far as the hilum (Fig. 946); from that it is carried to the stomach as the left layer of the **gastro-splenic ligament.** Similarly, the inferior layer of the left triangular ligament is continued down on the posterior part of the diaphragm to the œsophagus, the anterior and left sides of which it clothes. It also forms a little fold at the left of the œsophagus, known as the **gastro-phrenic ligament** (see p. 1163 and Fig. 912).

At the right side, the portion of the peritoneum which forms the inferior layer of the coronary ligament is carried down over the right kidney (and inferior part of the supra-renal gland) to the duodenum and right colic flexure, over both of which it passes.

We shall now follow down the peritoneum forming the posterior wall of the general peritoneal cavity—which we have already traced to the stomach—as seen in a sagittal section (Fig. 944).

Having reached the lesser curvature of the stomach, it passes down over the front of that organ, clothing it completely as far as the greater curvature. From that it descends, and is usually adherent to the transverse colon, forming the anterior layer of the gastro-colic ligament. Thence it passes onwards as the most anterior fold of the greater omentum. Arrived at the inferior border of the greater omentum, the membrane returns on itself, and passes upwards towards the transverse colon, forming the most posterior layer of the omentum. After covering the posterior aspect of the transverse colon (Fig. 944), it is continued, as the posterior layer of the transverse mesocolon, to the posterior abdominal wall, which it reaches at the anterior border of the pancreas (Fig. 944).

From the anterior border of the pancreas it is continued downwards again, clothing first the lower surface of the pancreas, then the front of the third portion of the duodenum, and, below that, the posterior abdominal wall. From the latter, however, it is soon carried forwards again by the branches of the superior mesenteric vessels passing to the small intestine. Running out along those, it forms the superior (or, more correctly, the right) layer of the obliquely placed mesentery (Fig. 944): on reaching the small bowel at the border of the mesentery, it invests that tube, giving it its serous coat, and then returns—as the inferior, or left, layer of the mesentery—to the posterior abdominal wall, on which it runs down, covering the great vessels near the median plane, and the psoas major muscle and ureter at each side, to enter the pelvis. The mesentery is described at p. 1198.

Pelvic Peritoneum.—The arrangement of the peritoneum in the pelvis minor is somewhat complicated, and is fully described in connexion with the several pelvic organs. A general account will suffice here.

Having passed over the superior aperture all round, it enters the pelvis minor, and covers its walls as low as the pelvic floor, across which it passes to the various organs. Behind, it invests the pelvic colon completely, and forms a mesentery

(pelvic mesocolon) for it, as far down as the third sacral vertebra. There the colon joins the rectum proper, and the complete investment of the bowel ceases.

As the end of the pelvic colon is approached the two layers of its mesocolon become shorter, and when the rectum is reached, they separate, leaving its posterior surface uncovered, whilst the bowel is clothed in front and at the sides. Lower down, the membrane leaves the sides, and finally, at a point which is usually about 3 inches (7·5 cm., see p. 1216) above the anus, it leaves the anterior surface of the bowel, and in the male is carried on to the posterior part of the bladder (here covered by the seminal vesicles and deferent ducts), forming the floor of the **excavatio recto-vesicalis (recto-vesical pouch)**, between those organs. It then covers the superior surface of the bladder, and passing off from its sides to the walls of the pelvis, constitutes the so-called false ligaments of the bladder. From the apex of the bladder it is carried on to the anterior abdominal wall by the middle

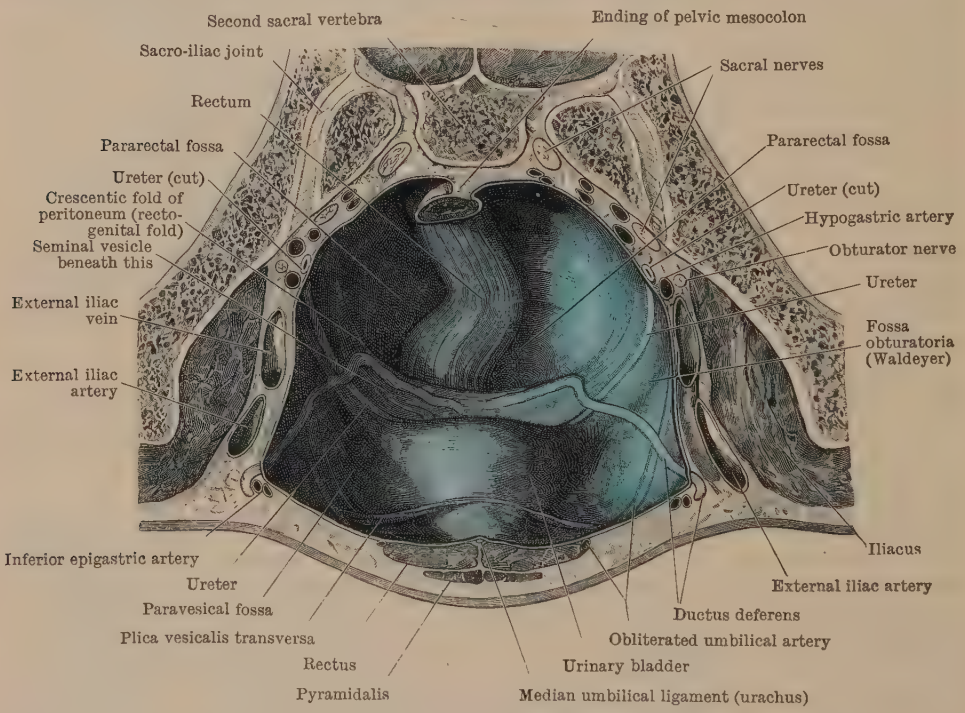

FIG. 945.—THE PERITONEUM OF THE PELVIC CAVITY.

The pelvis of a thin male subject aged 60 was sawn across obliquely. Owing to the absence of fat the various pelvic organs are visible through the peritoneum, though not quite so distinctly as represented here. The urinary bladder and rectum were both empty and contracted ; the paravesical and pararectal fossæ, as a result, are very well marked.

umbilical ligament, thus forming the **plica pubovesicalis** (O.T. the **superior** or **anterior false ligament** of the bladder).

In the female (Fig. 944), the peritoneum, on leaving the rectum, passes to the posterior wall of the vagina, the superior portion of which it covers. From that it is continued up over the posterior surface and fundus of the uterus, and down on its anterior surface as far as the junction of the cervix and body (Fig. 944). Here it passes from the uterus to the bladder, which it partly covers, as in the male, and is then carried on to the anterior abdominal wall. Between the rectum behind, and the uterus and vagina in front, is situated the **excavatio rectouterina [cavum Douglasi]** (O.T. **pouch of Douglas**), the entrance of which is limited, on each side, by a fold passing from the cervix of the uterus around the sides of the pouch towards the rectum; these are the **plicæ rectouterinæ [Douglasi]**, and they contain in their interior the **musculi rectouterini**, two bands of fibrous tissue with plain muscle fibres intermixed, which pass from the cervix of the uterus, backwards

on each side of the rectum, to blend with the connective tissue on the front of the lower part of the sacrum.

Similarly, in front of the uterus, between it and the bladder, is found the much smaller **excavatio vesico-uterina (utero-vesical pouch)**. Finally, the peritoneum is prolonged as a wide fold from each margin of the uterus to the side wall of the pelvis, constituting the **ligamentum latum uteri (broad ligament of the uterus)**, within which are contained the uterine tube, the ovary, the ligamentum teres, and other structures (see Uro-genital System).

When the bladder is empty, there is seen at each side, between it and the pelvic wall, a considerable peritoneal depression—the **paravesical fossa** (Fig. 945). This fossa is traversed by a peritoneal fold—the **plica vesicalis transversa**—which runs transversely laterally from the superior surface of the empty bladder, and, when well marked, passes to the neighbourhood of the abdominal inguinal ring.

Above the bladder, on each side of the middle umbilical ligament, is found the **internal inguinal fovea** already referred to (p. 1224). Both of these fossæ are practically obliterated by distension of the bladder.

Similarly, there is seen at each side of the empty rectum, on the posterior pelvic wall, a large depression, which may be known as the **pararectal fossa** (Fig. 945). When the rectum is empty and contracted, these fossæ are occupied by intestine; during distension, the rectum, increasing in width, expels the intestine and practically obliterates the fossæ.

Transverse Tracing of the Peritoneum.—If the peritoneum is followed transversely around the abdomen, just above the level of the iliac crest (Fig. 948), few difficulties will be encountered. From the anterior abdominal wall it passes round on each side to the back, lining the sides and the posterior wall. Passing medially on the posterior wall, it meets the colon—ascending on the right side, descending on the left—over which it is carried, in each case covering the bowel in front and at the sides only, and leaving the posterior surface bare, as a rule. Sometimes, however, the covering is complete, and a short mesentery is formed. It is next continued *medially* over the psoas muscles, the ureters, and the great vessels, on the front of which it meets the superior mesenteric artery and vein running downwards to the intestines. From both sides it passes forwards on these vessels, forming the right and left layers of the mesentery; and finally, having reached the intestine, it clothes it completely, and the two portions become continuous on the bowel.

A transverse tracing at a higher level would include the bursa omentalis; it will, therefore, be well to study this portion of the peritoneal cavity before describing such a tracing.

Bursa Omentalis (O.T. **Lesser Sac of the Peritoneum**).—The **omental bursa**, as already pointed out, is a diverticulum of the great sac. It lies behind the stomach and adjacent organs, and communicates with the general cavity by a constricted passage, called the **foramen epiploicum [Winslow]**. If the general cavity is compared, as already suggested, to a bag, the anterior layer of which clothes the anterior wall and sides of the abdomen, and the posterior layer covers the viscera lying on the posterior wall, the bursa omentalis would correspond to a pocket lying behind the stomach, lesser omentum and part of the liver, and opening into its cavity by a narrow mouth, on the right side, just below the liver. From this opening the pocket passes to the left behind the lesser omentum and stomach, as far as the spleen, up behind the caudate lobe of the liver, and down behind the stomach and gastro-colic ligament.

As in the case of the general peritoneal cavity, it will, of course, be understood that the two walls of the bursa omentalis and the boundaries of the epiploic foramen are normally in contact. We shall first consider this opening, and then trace the layers of the omental bursa.

Foramen Epiploicum (Winslow) (Fig. 946).—This, the constricted passage which leads from the general peritoneal cavity into the bursa omentalis, is situated just below and behind the porta hepatis. It is *bounded anteriorly* by the right, free border of the hepato-duodenal ligament, passing up from the superior part of the duodenum to the porta hepatis, and containing between its two layers the portal vein, hepatic artery, and bile-duct. *Posteriorly*, lies the inferior vena cava, covered, of course, by peritoneum. *Above*, is placed the caudate process of

the liver. And *below*, lies the superior part of the duodenum with the hepatic artery running forwards and to the right beneath the foramen, before turning up into the lesser omentum. It should be remembered that, normally, the various

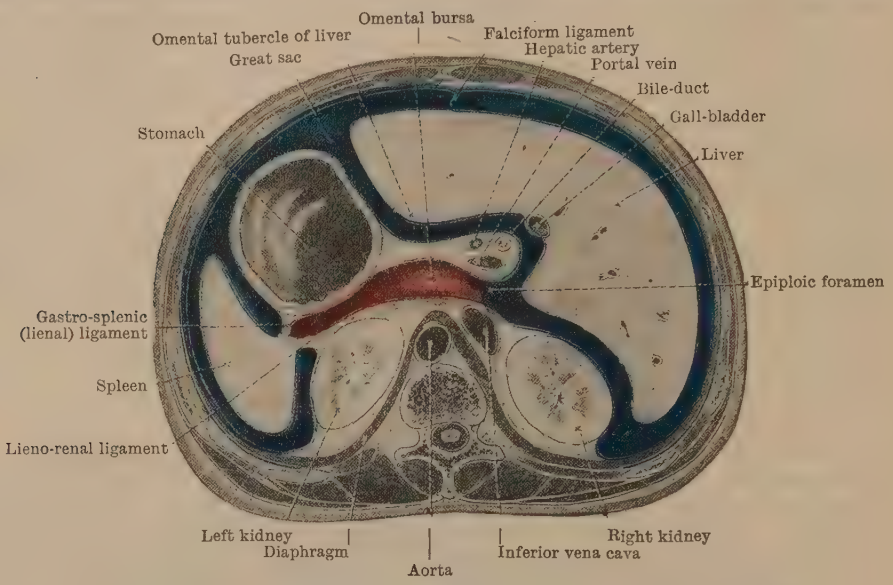

FIG. 946.—TRANSVERSE SECTION OF ABDOMEN AT LEVEL OF EPIPLOIC FORAMEN.

boundaries of the foramen lie in contact, and that its cavity can only be said to exist as such when its walls are drawn apart.

Beyond the foramen epiploicum is a small portion of the omental bursa termed the **vestibulum bursæ omentalis**, lying below the processus caudatus of the caudate lobe of the liver, and above the superior part of the duodenum and the head of the pancreas. The anterior wall of this portion is formed by the hepato-duodenal ligament, with the bile-duct, hepatic artery, and portal vein. The

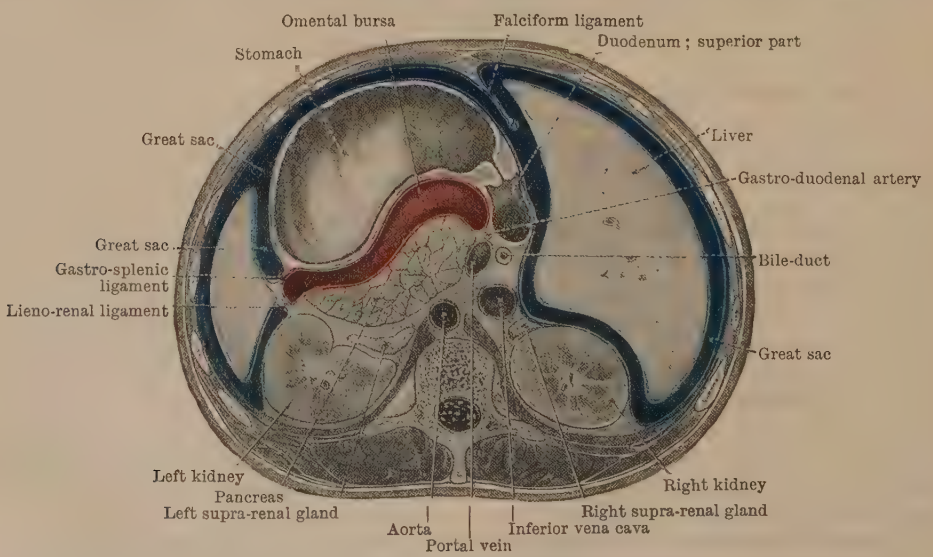

FIG. 947.—TRANSVERSE SECTION OF ABDOMEN IMMEDIATELY BELOW EPIPLOIC FORAMEN.

vestibule is continued beyond a fold termed the **plica gastropancreatica** into the true bursa omentalis, which presents two main parts, the recessus superior and recessus inferior. The **recessus superior** passes from the vestibule upwards behind the porta hepatis to the dorsal surface of the lobus caudatus. Posteriorly it is in

contact with the diaphragm and aorta. The **recessus inferior** extends medially in front of the pancreas, and behind the stomach, and passes to the left towards the spleen as the **recessus lienalis.**

The recessus inferior omentalis and the vestibulum bursæ omentalis communicate with one another by a rounded orifice, which is constricted by the sickle-shaped forward projecting fold, the plica gastropancreatica. This fold is an elevation of the peritoneum of the posterior wall of the omental bursa, raised up by the arteries of the stomach as they pass forwards to that organ from the posterior wall.

As the peritoneal wall of the omental bursa is described in two main parts, an anterior and a posterior, it will be necessary to follow each of these separately. Above, the peritoneum forming the **anterior wall** clothes the caudate lobe; it then passes down (from the posterior margin of the porta hepatis, and the fossa of the ductus venosus) to the lesser curvature of the stomach and the duodenum as the posterior layer of the lesser omentum. Continued on from this, it clothes the posterior (or visceral) surface of the stomach as far as the greater curvature, with the exception of the small "uncovered area" below and to the left of the cardia (Fig. 949), but it does not actually come in contact with the œsophagus

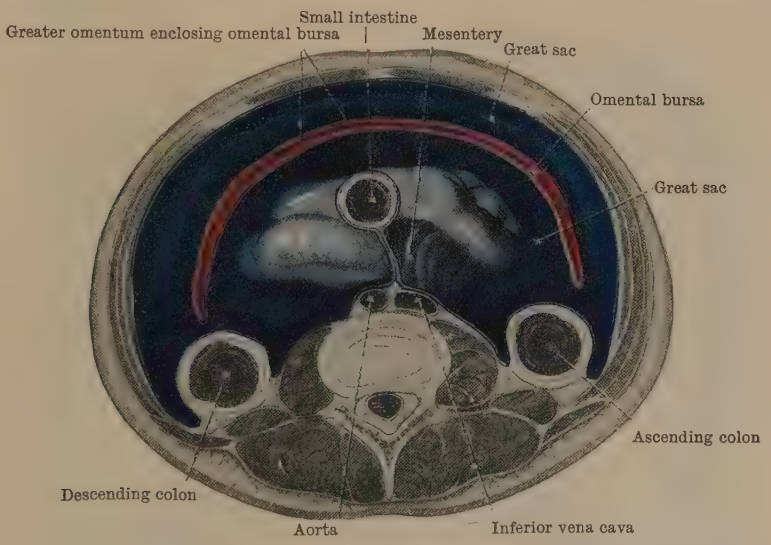

Fig. 948.—Transverse Section of Abdomen through the Fourth Lumbar Vertebra.

itself, the back and right side of which are uncovered. On the left, it is reflected from the back of the stomach to the spleen as the deeper layer of the gastro-splenic ligament.

From the greater curvature of the stomach it is continued down, forming the posterior layer of the gastro-colic ligament as far as to the transverse colon. In some cases it is not attached to the colon, but is continued onwards as the posterior of the anterior two layers of the omentum, and in such cases at the inferior part of the omentum it meets and becomes continuous with the posterior layer of the omental bursa.

The peritoneum forming the **posterior wall of the bursa omentalis**, in passing through the epiploic foramen, clothes the front of the inferior vena cava (Fig. 946); beyond this, it covers the cœliac artery, and passes upwards to line the slight depression on the posterior abdominal wall (diaphragm), against which the caudate lobe rests. Then, passing over to the left, it covers the superior surface of the pancreas, the top of the left kidney and suprarenal gland, and the medial part of the gastric surface of the spleen (Fig. 946). From the anterior border of the pancreas it is prolonged anteriorly and downwards—as the anterior or upper layer of the transverse mesocolon—to the transverse colon (Fig. 944). Here it usually joins the gastro-colic ligament, but in English text-books it is described, and here it is figured, as being continued down as the anterior layer of the posterior fold of

the greater omentum, almost to its inferior border, where it becomes continuous with the anterior layer of the omental bursa already described.

The transverse tracings at the level of the epiploic foramen and pylorus are shown in Figs. 926 and 946, and can be easily followed without any further description than is there given.

The **lesser omentum** is described at p. 1155; it need only be pointed out now that it is composed of two layers, the anterior belonging to the general peritoneal cavity, and the posterior belonging to the omental bursa; and both layers are extremely thin—sometimes even cribriform.

The **greater omentum** is a large apron-like fold of peritoneum, usually more

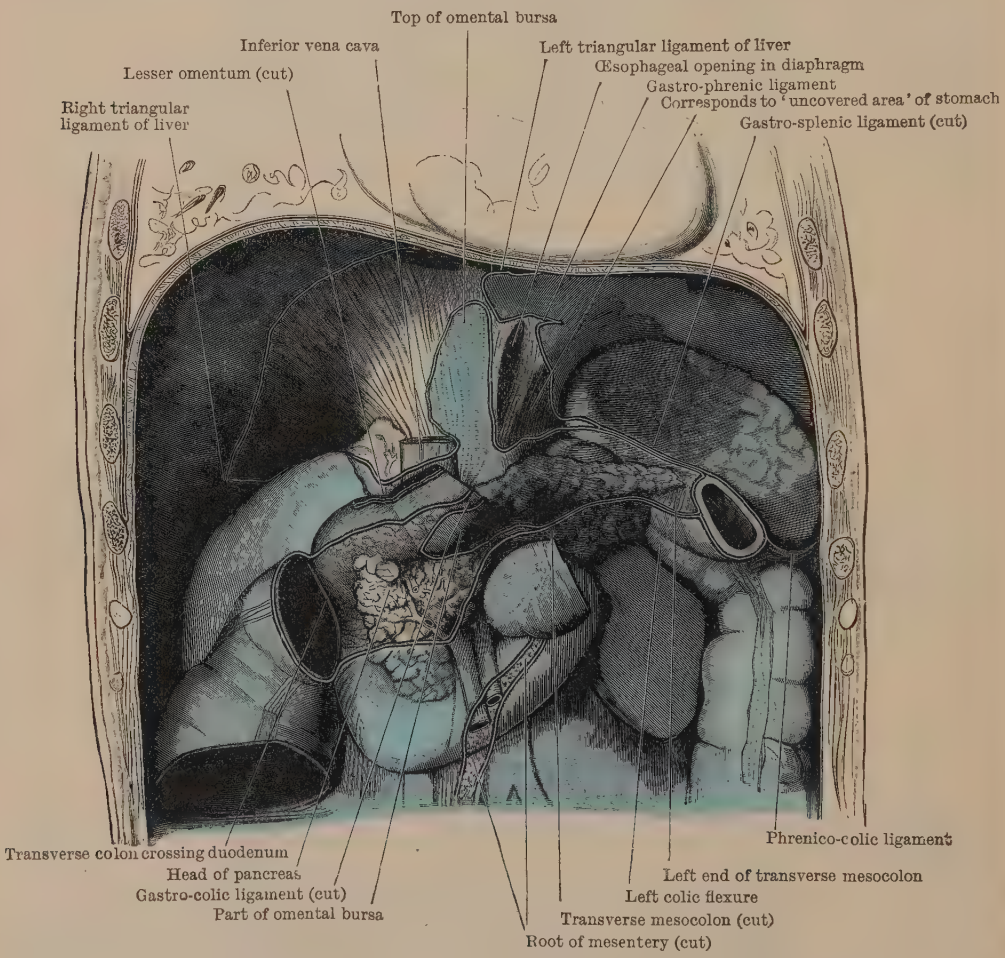

FIG. 949.—THE PERITONEAL RELATIONS OF THE DUODENUM, PANCREAS, SPLEEN, KIDNEYS, ETC.

or less loaded with fat, which is suspended from the transverse colon, and hangs down in front of the intestines to a variable extent. When the abdomen is carefully opened without disturbing the viscera, it is rare to find the greater omentum evenly spread over the front of the intestines. More commonly it is folded in between some of the coils of intestine, or tucked into the left hypochondrium; or perhaps it is carried upwards in front of the stomach by a distended transverse colon. The gastro-colic ligament continues the anterior layers of the greater omentum upwards to the stomach, and the gastro-lienal ligament continues them between the spleen and stomach. The greater omentum is thus commonly described as extending between the greater curvature of the stomach above and the transverse colon below, not taking the shortest course from one of these to the other, but hanging down as a loose fold between the two, and containing

between the anterior and posterior folds a cavity continuous with the omental bursa (Fig. 944).

This is the condition in the embryo, but in the adult the anterior fold usually becomes adherent to the colon, and, below it, also to the posterior fold, and hence the cavity becomes largely obliterated. If the gastro-colic ligament be included as part of the greater omentum, and the embryonic condition is retained, as is usually described in English text-books, the greater omentum may be said to consist of two folds, each formed of two layers, one derived from each sac of the peritoneum. The **anterior** or **descending fold** begins at the greater curvature of the stomach, where it is formed by the meeting of the two layers from the anterior and posterior surfaces of that organ respectively; from there it descends to the front of the transverse colon. Leaving the colon, or passing anterior to it (see Fig. 944), the two layers proceed to the lower border of the omentum, where, turning back (Fig. 944), they pass up as the **posterior** or **ascending fold.** That runs upwards until it meets the transverse colon; there its two layers separate to enclose and cover that colon—and the greater omentum, properly so called, ceases. Its two layers, however, unite at the superior margin of the colon (Fig. 944) to form the **transverse mesocolon**, which is continued upwards and posteriorly to the anterior border of the pancreas. There the layers of the transverse mesocolon again separate—the superior running upwards over the anterior surface of the pancreas to the posterior abdominal wall and lining the omental bursa; the lower passing downwards on the posterior abdominal wall, as already explained.

The greater omentum is continued to the right for a short distance (25 mm.) along the inferior border of the duodenum. At the left end it shortens very much, and is directly continued into the gastro-lienal ligament; the spleen, as it were, being introduced between the two layers instead of the colon.

Functions of the Greater Omentum.—Numerous uses have been assigned to the great omentum; the chief seem to be: (1) To act as a movable and easily adjustable packing material, capable of filling all temporarily-produced spaces in the abdomen. In this respect it may be compared with the Haversian fatty pads in joints. (2) It probably, to some extent, prevents the passage of the small intestines up into the stomach chamber, and helps to keep them from getting entangled there. (3) It is a storehouse of fat. (4) It is said to be "the great protector against peritoneal infectious invasions." Being freely movable, it can pass to almost any part of the abdomen, and there "build up barriers of exudations to check infection."

Mr. Lockwood has made the interesting observation (in connexion with the contents of herniæ) that, in bodies under forty-five years of age, the omentum can rarely be drawn down below the level of the pubic tubercle; in older bodies the reverse is the rule.

The **gastro-lienal ligament** is a short fold composed of two layers—an anterior, lining the general peritoneal sac, and a posterior, lining the omental bursa (Fig. 946). It is attached by one margin to the fundus and greater curvature of the stomach, and by the other to the gastric surface of the spleen just in front of the hilum. Between its two layers the vasa brevia of the splenic artery pass from the spleen to the stomach. Below and in front, its layers are continued into the corresponding layers of the gastro-colic ligament; above and behind, they separate at the "uncovered area" of the stomach (Fig. 949).

Minor Folds of Peritoneum.—The **phrenico-colic ligament**, passing from the left flexure of the colon to the diaphragm opposite the 10th or 11th ribs, has been described, and also the mesentery of the vermiform process, the lieno-renal and hepato-renal ligaments.

DEVELOPMENT OF THE DIGESTIVE SYSTEM.

In the section on General Embryology it has been pointed out that the alimentary canal is formed from three separate parts: (1) A middle large entodermal portion, and (2) two smaller ectodermal parts, one anterior, the oral sinus or stomatodæum, and one posterior, the proctodæum.

It has been further shown that the three portions are at first separated from one another by septa, the pharyngeal membrane and the proctodæal membrane, respectively, but the septa disappear at an early date, and the three parts are thrown into continuity.

There is thus formed a tube, the primitive alimentary canal, extending through the body from the mouth aperture in front to the anal orifice posteriorly.

The entodermal segment of the primitive alimentary canal is derived from the dorsal portion of the yolk sac and divided into three portions as follows:—

That portion which is enclosed within the head fold is termed the foregut; the portion within the tail fold is termed the hindgut; and the intermediate portion is termed the midgut. The midgut at first lies opposite the communication with the yolk sac, and the other portions cephalic to and caudal to this level.

From the foregut are formed the posterior part of the mouth, the pharynx, œsophagus, stomach, and the greater part of the duodenum. From the mid and hindgut are formed the rest of the small intestine, and the whole of the large intestine, as far as to the "white line" of the anal orifice. There is no sharp limit between the mid and hindgut or between the portions of the intestinal canal formed from them.

This primitive intestinal tube forms the basis, not only of the alimentary canal and its associated organs, but it also is the source from which many other organs, not ultimately connected with digestion, are formed.

Thus, the respiratory tract below the level of the orifice of the larynx is formed as an outgrowth from the ventral wall of the primitive foregut, and remains permanently connected with it at that point, though in structure and function it becomes very different from the tube from which it is derived.

Other structures also, namely, the thyreoid gland, the parathyreoid glands, and the thymus, are formed as diverticula of the primitive pharynx, but they eventually lose their connexion with the wall of the tube.

Furthermore, the allantois, a diverticulum from the hindgut, and a part of the primitive hindgut is cut off from the primitive cloaca to form the urinary bladder and a portion of the urethra.

Accounts of the development of the organs mentioned which are not connected with the alimentary canal in the adult will be found in the sections dealing with them.

Development of Mouth and Pharynx.—The development of the mouth and of the pharynx from the oral sinus and anterior part of the foregut are intimately associated with one another, and with the formation of the mouth and nose.

The stomatodæum or oral sinus is a depression situated between the primitive forebrain above and the pericardial region below.

The floor of this depression is formed by the pharyngeal membrane, which consists of ectoderm and entoderm only, mesoderm being absent; the membrane separates the oral sinus from the anterior end of the foregut, but at an early stage it ruptures and disappears.

The mouth cavity of the adult is formed in part from the oral sinus, and in part from the anterior end of the foregut, or primitive pharynx. The line of division between the portions of the mouth derived from these two parts is difficult to trace, on account of the very extensive changes which occur after the pharyngeal membrane has disappeared, and which are associated with the formation of the face and of the nose. The portion of the mouth cavity derived from the primitive pharynx is lined with entoderm, and that from the oral sinus with ectoderm. The position of the original pharyngeal membrane may be represented by an imaginary plane extending from the anterior part of the body of the sphenoid to the base of the alveolar process of the mandible on its lingual surface.

Thus, the cavity of the nose is derived from the upper part of the oral sinus, while the floor of the mouth is formed from the pharynx. The adamant (O.T. enamel) of the teeth and the secreting epithelium of the parotid gland are ectodermal structures, while the epithelium of the tongue and submaxillary and sublingual glands is entodermal in origin.

The ectodermal or oral sinus portion of the mouth, then, gives origin to the lips, teeth, and parotid glands; while in the pharyngeal portion are developed the tongue, submaxillary and sublingual glands.

The **upper lip** is formed from the tissues covering the frontal and maxillary processes (see development of face).

The **lower lip** similarly is formed from the tissues covering the mandibular arches.

By an ingrowth of epithelium from the surface of the frontal and maxillary processes into the subjacent mesoderm and by subsequent desquamation of the superficial layers, a groove is formed between the lips and cheeks on the one hand, and the alveolar ridges on the other. This groove when deepened forms the vestibule of the mouth, and is termed the alveolo-labial sulcus, or labial groove.

The surface covered with mucous membrane becomes everted, to form the red portion of the lips, and at birth is divided into an outer smooth portion, and an inner portion whose surface is villous, termed pars villosa. The distinction between these two parts disappears shortly after birth.

Several explanations of the formation of the **philtrum** or groove on the front of the upper lip have been put forward; most probably it is produced by the union of the margins of the two processus globulares with one another, the floor of the groove being formed by their line of union, and the ridges bounding the groove at the sides corresponding to the medial portions of the globular processes.

The **parotid glands** are formed as outgrowths of the epithelium in the outer wall of the alveolo-labial sulcus.

The outgrowth in each side has been found in embryos 8 mm. long. It is at first a furrow. The posterior part of the furrow becomes closed off from the mouth cavity and forms a tube, which grows backwards for some distance on the surface of the first visceral arch.

The terminal portion of the tube formed in this way gives rise to a number of buds, which divide repeatedly, and form the lobules of the gland.

These are at first solid, and the alveoli do not become hollowed until about the twenty-second week.

The epithelium of the terminal buds forms the secreting glandular epithelium, while that of the stalk forms the lining epithelium of the duct.

Development of the Teeth.

Development of Human Teeth.—The following is a brief summary of the chief events in the development of a human tooth. For convenience in expression and terms, the description refers to the development of a lower tooth. The upper teeth are, of course, developed in a manner exactly similar.

1. The first distinct evidence of the development of the teeth is to be found in a thickening of the mouth epithelium at the site of the future gum, and a downgrowth of its deeper portion into the substance of the primitive jaw (Fig. 950, I.). This epithelial downgrowth is continued along the whole length of the gum, and is known as the **dental lamina** or **tooth-band.** The dental lamina divides into two plates, a lateral vertical and a medial more horizontal in direction. The medial plate is the portion from which the teeth are formed, and is termed the **dental ledge.** On the under surface of the dental ledge there soon appears a series of knob-like projections—one for each of the milk teeth (Fig. 950, II.)—which are known as **adamant germs** or **adamant organs.** These organs are connected with the epithelium of the dental ledge by a constricted part, and although at first knob-like, they soon become bell-shaped owing to the invagination of the lower surface of the knobs, so that each may now be compared to an inverted egg-cup.

2. As soon as the adamant organs begin to assume a cup-like shape, the cellular connective tissue of the jaw beneath grows up and projects into the cavity of the cup (Fig. 950, III.) in the form of a papilla—the **papilla dentis.** The arrangement, pursuing our simile, may now be compared to an egg fitting into its cup—the papilla representing the egg, and the adamant organ the cup (Fig. 950, III.).

The adamant organ is a rounded sac, with an invaginated base. Three portions may be recognised in it: (1) An internal layer covering the surface of the papilla, termed the adamant membrane, from which the adamant is formed; (2) an external layer, in contact with the surrounding connective tissue; and (3) an intermediate portion which occupies the interior of the sac, and is soft and gelatinous in consistence and ultimately disappears.

3. The epithelial cells lining the concavity of the adamant organ, and the superficial cells of the tooth papilla, become elongated or columnar, and undergo other changes, preliminary to the production of the adamant by the former—which are now called **adamant cells** or **ameloblasts**—and the ivory by the latter, which are known as **odontoblasts.**

4. The **odontoblasts** form at their outer ends a layer of ivory (Fig. 950, IV.). Similarly, the adamant cells lining the cup form at their inner surface a layer of adamant on the top of the layer of ivory (Fig. 950, IV.), to which it adheres: in each case the deposit taking place first at the summit of the tooth.

5. The formation of these tissues proceeds apace, the ivory increasing at the expense of the papilla, the adamant similarly encroaching on the cup or adamant organ; and in each case the two layers of cells—odontoblasts and adamant cells—which produced the deposits retiring gradually from one another, as the space between them becomes occupied by the newly formed tissues (Fig. 950, V.).

The remains of the dental papilla persist as the **pulp** of the tooth, which is covered even in the adult by the odontoblasts, and occupies the **tooth cavity,** *i.e.* the central part of the tooth to which the formation of ivory has not extended.

6. Turning now to the jaw itself: The connective tissue of the gum surrounding the **tooth germ** (as the developing tooth with its adamant organ and dental papilla are called) early becomes condensed and vascular (Fig. 950, V.), and later on forms a membranous bag—the **tooth-sac** or **follicle**—which completely shuts off the developing tooth from the surrounding structures. On the floor of the sac the tooth germ sits, the base of its dental papilla being continuous with the tissue of the floor of the sac, and the young tooth being enclosed by the sac as a kernel is enclosed by its shell.

7. Reverting to the tooth: When the crown is completed the formation of ivory is continued downwards to form the **root.** As the ivory is formed, and the root is built up, the connective tissue of the tooth-sac comes to surround the root more closely, and deposits on its surface, after the manner of a periosteum, a layer of bone, the **substantia ossea.** After that layer has been formed, the connective tissue of the sac persists as the **alveolar periosteum.** The development of the root takes place very slowly, and its lower end is not completed as a rule for some time after the eruption of the tooth has taken place.

8. During the development of the teeth the ossification of the jaw has been going on, and as it grows up on each side, the young teeth, enclosed in their tooth-sacs, come to lie in an open bony groove, which is subsequently divided by septa into compartments—the **alveoli**—for the individual tooth-sacs. The bone continuing to grow after birth, these compartments become more perfect, but are never entirely closed in over the crowns of the teeth. During the eruption of the teeth the upper and anterior part of each of the bony cells is absorbed; subsequently, however, it is re-formed around each tooth when it has taken its final position.

9. **Eruption.**—Long before the root is completed, the crown, by some force which is not properly understood, but which does not seem to depend on additions to the root, is pushed

through the top of the tooth-sac, and—the upper and anterior wall of the roomy alveolus having been absorbed at the same time—onwards through the gum until the mouth is reached. Later, when the tooth has assumed its final position, the alveolus, as already stated, is re-formed, and closely embraces the completed root.

10. After the adamant organs of the deciduous teeth have been formed on the inferior aspect of the dental lamina, as described above, the neck of epithelium by which the lamina is still connected with the surface becomes broken up into a cribriform sheet. Its free posterior border, on the other hand, continues to grow inwards in the tissue of the gum towards the cavity of the mouth (Fig. 950, III. and IV.), and at a later date there appear on its under surface, near the free edge, and behind the several developing milk teeth, the adamant organs—or so-called "reserve germs"—for the corresponding **permanent teeth**, which are developed in exactly the same manner as the deciduous teeth described above.

In connexion with the development of the **permanent molars**, which have no corresponding teeth in the deciduous set, there takes place a prolongation backwards of the posterior extremity of the dental lamina into the tissue of the jaw, behind the last deciduous molar. On the inferior aspect of this prolongation, which has no direct connexion with the surface epithelium, adamant organs are formed for the permanent molars, and their further development goes on in the manner described for the other teeth.

The *dates* at which some of the chief events in the development of the teeth occur may be briefly given: The thickening of the epithelium, the first sign of the future teeth, begins about the sixth week of fœtal life, and the dental lamina is completed by the end of the seventh week.

The dental papillæ for the eight front teeth appear and become surrounded by their adamant organs about the tenth week, and the papilla for the first permanent molar about the seventeenth week.

The first traces of calcification, and the formation of the tooth-sacs, take place about the fifth month of fœtal life.

Formation of Adamant and Ivory.—Different opinions are held as to the method in which the **substantia adamantina** is produced by the cells concerned in the process. One view maintains that it is secreted and shed out by the cells (Kölliker). According to the other view, part of the substance of the cells is actually converted or transformed into adamant (Tomes). In connexion with this latter view, which seems to receive more support at present, Tomes has discovered that there projects from the base of each cell, towards or into the most recently formed enamel, a fibrillar process, which has received the name of **Tomes' process**, and he holds that the substantia adamantina is formed by calcification taking place in or around the process.

I. Shows the downgrowth of the dental lamina D.L from the surface epithelium E and the beginning of the adamant germ E.G.

II. Shows the further growth of the adamant germ and its invagination.

III. The adamant germ is more invaginated, and its inner layer of cells becomes columnar. A, the dental lamina, grows thinner, but near its posterior or lingual edge there is an enlargement R.G which is the reserve germ for a permanent tooth. The superficial cells of the ivory papilla P are becoming columnar.

IV. The inner columnar cells of the adamant germ (called adamant cells) A have formed a cap of adamant EN, inside which the superficial cells of the papilla, the odontoblasts O, have formed a layer of ivory D.

V. Shows a more advanced stage still. The deposit of ivory is extending downwards, and enclosing the papilla to form the future pulp, in which a vessel V is seen.

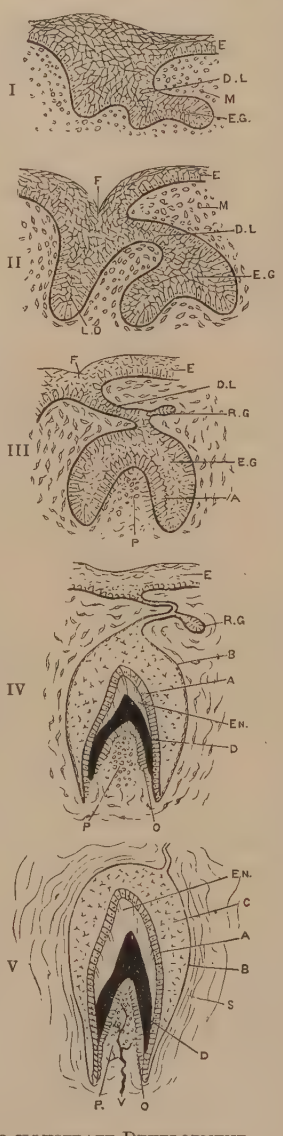

FIG. 950.—DIAGRAM TO ILLUSTRATE DEVELOPMENT OF A TOOTH.

A, Inner layer of adamant germ; B, Outer layer; C, Remains of internediate cells; D, Ivory; D.L, Ivory lamina; E, Epithelium; E.G, Adamant germ; EN, Adamant; F, Dental furrow; L.D, Labio-dental furrow; M, Connective tissue cells; O, Odontoblasts; P, Ivory papilla; R.G, Reserve germ; V, Blood-vessel.

Similarly, two views are held as to the production of ivory by the odontoblasts: one, that the odontoblasts secrete the matrix ivory, and the other, that their substance is actually converted into the matrix of the ivory. The odontoblasts, when active, are branched columnar-shaped cells, and from their outer ends one or more processes extend towards and into the ivory; between these processes a matrix appears—produced probably by the odontoblasts—and soon this matrix becomes calcified. In this way the ivory is formed, and the process is repeated until its full thickness is attained. The branches of the odontoblasts, encased in ivory, just mentioned, are the Tomes' fibrils already described; the canals in which they lie are the dental canaliculi;

and the fibrils themselves are concerned in the production of the sheaths of Neumann which line the tubes.

The **tooth-sacs**, when fully developed, are large and distinct fibrous bags which lie in the alveoli of the maxilla and mandible, and are continuous above with the tissue of the gum. On the lingual side of the sacs of the deciduous teeth are found the germs of the permanent teeth, surrounded by their own sacs. These latter are at first very small, and are partly embedded in the posterior wall of the deciduous tooth-sacs, but subsequently they come to lie in distinct but incomplete bony cavities of their own. The bone surrounding the tooth-sacs, temporary and permanent, is always wanting over the summit of the sac, and the band of connective tissue by which the sac is connected with the overlying gum tissue, through the deficiency, is known as the **gubernaculum dentis.**

All the points mentioned are easily demonstrated on the mandible of a child at birth, particularly when the tissues have been allowed to soften a little. If, in such a specimen, the gum and periosteum are reflected upwards from the labial and lingual surfaces of the mandible, and freed as far as the superior border of the jaw, the gum, with the tooth-sacs depending from it like small bags, can be pulled away out of the bony groove of the jaw; and if the operation has been successfully performed, the tooth-sacs of the three front permanent teeth may be seen, varying in size from a small pin's-head to a hemp-seed, hanging down behind the superior part of the corresponding deciduous sacs. As already explained, the tooth-sacs are produced simply by a condensation of the connective tissue around the developing tooth, the condensation going on to the formation of a distinct membranous bag.

Eruption of the Teeth.—When the eruption of the deciduous teeth is about to take place, the anterior wall and roof of the alveolus are absorbed; the tooth passes through the sac and appears above the gum, and then the alveolus, which up to this was much too large to give actual support, is re-formed more closely around the tooth. Meanwhile the root, which was only partly formed at the time of the eruption, continues to be added to, possibly for a few years more, and, as it grows, the alveolus is completed around it. When the permanent tooth, or as much of it as is then formed, is about to be erupted, it makes its way from its own bony cell through the posterior wall of the alveolus of its temporary predecessor; the root of the deciduous tooth undergoes absorption at the same time, but quite independently of pressure from the permanent tooth. The alveolus, now occupied by both teeth, is again much enlarged by absorption, particularly in front; what remains of the temporary tooth is shed; the permanent tooth passes onwards through the enlarged alveolus, and, making its way to the surface, appears above the gum. After some time, when the tooth has taken its final position, the alveolus is again re-formed, first around its neck, and later on, as the root is built up, around it also, and thus the tooth is permanently fixed.

What the force is which causes the eruption, is a question that has not been answered satisfactorily. That the growth of the root pushes up the crown was formerly the favourite explanation. For several reasons, unnecessary to detail, this view is now discarded, and a theory which attributes the impelling force to the blood pressure is looked upon with more favour, although even this is not altogether satisfactory. (See Tomes' *Dental Anatomy*, 5th edition, page 211.)

Morphology of the Teeth.

In most vertebrates below mammals all the teeth are alike in form; such a dentition is said to be **homodont.** In the majority of mammals, on the other hand, the teeth are arranged in groups of different size and form; such a dentition is **heterodont.**

Again, mammals have, neglecting exceptional cases, but two functional sets of teeth; they are consequently said to be **diphyodont.** Most vertebrates below mammals, on the other hand, have a continuous succession of teeth throughout life, and hence are said to be **polyphyodont.**

Seeing that practically all lower vertebrates are provided with simple conical teeth, the evolution of the multi-tuberculate mammalian molar has given rise to much speculation. The jaws of the earliest fossil mammals found are furnished with tri-tubercular teeth, the three tubercles being placed in an antero-posterior line; by a rotation of two of the tubercles to the lingual or labial side, as the case may be (a condition found in certain other fossil skulls), we arrive at a tri-tubercular form, from which the transition to an ordinary mammalian molar is not difficult. As to how the tri-tubercular tooth arose from the simple cone, two different views are advanced: one, that it was formed by the union of several conical teeth as a result of the shortening of the jaw and the crowding of the teeth together; the other, that the single conical tooth developed on its crown two subsidiary tubercles, one in front and the other behind, and that these tubercles growing larger, the tooth assumed the tri-tubercular form.

The complete or **typical mammalian dentition**, in its highest development, as in the horse, is represented by the following formula: i. $\frac{3}{3}$, c. $\frac{1}{1}$, pm. $\frac{4}{4}$, m. $\frac{3}{3}=44$. In the dentition of man, therefore, one incisor and two premolars are wanting. Different views are held as to which teeth have been suppressed—most probably they are the second incisors, and the first and second or first and last premolars.

In general it may be said that the **dentition of the lower races** differs from that of the higher, in that the dental arches are squarer in front, the teeth larger and more regular, the canines stronger, the last molars better developed, and the tubercles on the molars more perfect, in the lower than in the more civilised races. It may be mentioned that the teeth of a savage man, if seen in the mouth of a European, would be looked upon as an "exceedingly perfectly formed set of teeth" (Tomes).

To express the proportion in size of the crowns of the premolars and molars to that of the skull in different races, Flower compared the distance from the front of the first premolar to the back of the last molar, *in situ*, with the distance from the front of the foramen magnum to the naso-frontal suture (basi-nasal length), in the form of a "dental index"—

$$\text{Thus: } \frac{\text{Length of teeth} \times 100}{\text{Basi-nasal length}} = \text{Dental index,}$$

and by this means he has divided the various races into **microdont** (index 42 to 43, Europeans, Egyptians, etc.), **mesodont** (index 43 to 44, Chinese, American Indians, Negroes, etc.), and **macrodont** (index 44 and upwards, Australians, Melanesians, etc.).

Development of Primitive Pharynx and Pharyngeal Portion of the Mouth.

The anterior blind termination of the foregut in the head region constitutes the primitive pharynx.

Its roof is formed by the tissues covering the under aspect of the mid- and fore-brain, and its floor by the tissues overlying the heart and pericardium. Each side wall is a lamina of tissue extending from the floor to the roof, continuous, in front, with the bucco-pharyngeal membrane, which forms the anterior wall of the pharynx and separates it from the stomatodæum.

In the roof are formed the tissues which form the hinder part of the base of the skull.

In the side wall and in the floor extensive changes occur, connected with the appearance of structures known as the visceral arches and pouches, and with the origin of numerous structures from them and the development of the tongue.

Tongue.—The tongue is formed in two portions, anterior and posterior, in the floor of the pharynx.

The anterior portion, forming the anterior two-thirds of the organ, is formed from the tissues on each side of the tuberculum impar, which grow up and enclose that elevation, and from the tuberculum itself. Evidence of this bilateral origin of the tongue is found in those cases of bifid tongue which occur, though rarely.

The hinder portion, forming the posterior third of the tongue, is formed from the tissues covering the inner ends of the second pair of arches (see p. 51).

These arches, as has been pointed out, meet and fuse in a common mass in front of the furcula, in the floor of the sinus arcuatus.

Between the ridge which they form and the tuberculum impar in front, a slight median depression is found, from which the median thyreoid diverticulum is formed, and which persists as the foramen cæcum of the tongue. On each side of this depression a groove runs obliquely laterally and upwards (the sulcus terminalis) immediately behind the region of the vallate papillæ, and marks the union of the anterior and posterior portions of the tongue.

The tongue mass formed by the union of these different parts increases in size, rises upwards from the floor of the pharynx, and projects forwards.

The tissue forming its interior becomes transformed into the muscular substance of the tongue, and is derived largely from the first branchial region, and not from the musculature of the visceral arches.

The investing epithelium of the anterior two-thirds gives rise to the papillæ and the taste buds, while that covering the posterior portion remains smooth. The papillæ appear about the third month as elevations of the corium, covered with epithelium.

The vallate papillæ are formed by ingrowths of the epithelium in rings, around a central core. The superficial layers of the epithelium desquamate and form the trench surrounding the papilla.

Submaxillary and Sublingual Glands.—These glands are formed in the alveolo-lingual groove in the floor of the primitive pharynx, immediately behind the first arch, by outgrowths somewhat similar to those described in connexion with the parotid (p. 1232).

The submaxillary outgrowths occur about the fifth week, and the sublingual, several in number, on the outer side of it at the ninth week.

Palatine Tonsil.—The glosso-palatine arch arises in the position occupied earlier by the second visceral arch, behind which, in the embryo, lies the pharyngeal portion of the second visceral cleft. The dorsal extremity of that cleft enlarges, and forms a recess termed the sinus tonsillaris. From the lower and greater part of the sinus tonsillaris the palatine tonsil is developed; the upper part of the sinus persists, however, as the supra-tonsillar fossa. The palatine tonsil at first is a smooth depression of the mucous membrane. About the fourth month of fœtal life downgrowths of the epithelium take place, which are afterwards converted into the tonsillar crypts. Subsequently lymph cells accumulate around the downgrowths and form the lymph tissue, which constitutes the mass of the organ. The plica triangularis is formed from a tubercle, which becomes flattened, and forms a fold on the anterior and medial aspect of the inferior part of the palatine tonsil.

Development of Œsophagus, Stomach, and Intestines.

1. **Development of the Tissues of the Œsophagus, Stomach, and Intestine.**—The wall of these portions of the intestinal tube consists at first of an internal lining of epithelial entodermal

cells, several layers thick, and of an external investment of mesenchyme. The intra-abdominal portion of the tube has also a partial external covering of flattened cells which form the lining wall of the cœlom.

The epithelial lining gives rise to the entire lining of the adult intestine, whether squamous, as in the œsophagus, columnar as in the stomach and intestine, and to the secreting cells of all the glands of the canal, including the liver and pancreas, as well as to the epithelial lining of the ducts of these and other glands.

The epithelium may be ciliated for a time in the œsophagus, and in the duodenum it may be so thickened as to obliterate for a time the lumen of the tube.

The epithelium shows early very active proliferation, so that ridges and furrows are formed, and the glands arise from downgrowth of the epithelium into, or in the case of the duodenal glands, through the substance of the underlying mesenchyme. In both the large and small intestine, the longitudinal ridges become broken up into isolated, finger-like stalks which form villi, and these are present for some time in the large as well as in the small intestine.

Additional villi are formed later on by a rapid growth of the epithelium in the intervals between the original villi.

The plicæ circulares of the intestine are formed much later, but are well formed at birth.

The **muscular coats** are formed from the mesenchyme by a gradual extension and modification of the cells forming it, by which the multi-nucleated fibrils of non-striped muscle are formed.

The circular coat is the first to originate, and later the longitudinal coat. In the colon this latter coat is formed first at the rectal end and thence spreads headwards, and it is from the first in the form of three separate longitudinal bands, while in the small intestine it is a continuous sheet.

Vessels and Nerves.—The nerves and probably also the vessels, both blood and lymph, grow into the wall of the intestine, the nerves from the neural tube and the vessels from the primitive vascular network connected with the yolk sac. It is, however, possible that both the nerve plexuses and the blood and lymph vessels are formed by a differentiation of the local tissue. The cœliac axis and the superior and inferior mesenteric arteries represent segmented vessels distributed to successive segments of the tube and to the organs derived from these segments. The branches of the vagi and sympathetic nerves grow into the intestinal wall from without.

Formation of Gastric and Intestinal Glands, etc.—The epithelial lining of the intestinal tube is composed, at first, of a single layer of cells, and the inner surface is smooth. In the second month the epithelium increases rapidly, and as a result its surface is thrown into folds and furrows, arranged irregularly. Mesenchymal tissue passes into the interior of the folds, and also blood capillaries. The folds appear first in the stomach, especially in the regions of the curvatures, and later in the duodenum and small intestine, and then in the large intestine, where they are formed first in the rectum and last in the vermiform process. In the stomach the folds are arranged so as to surround small isolated depressions, which afterwards become the foveolæ gastricæ. In the small intestine isolated elevations are found, in place of continuous folds, and at a later stage new elevations are formed between the primary ones. These papillary elevations form the villi. In the large intestine, the arrangement resembles that in the stomach. The glands of the stomach and intestine, viz., the gastric and duodenal glands, and the intestinal glands in the small intestine are formed by an active proliferation of the epithelium at the bottom of the furrows, and at first the cells forming them are everywhere of a similar character, and become differentiated later on. In the stomach the formation of the glands begins about the end of the third month.

The intestinal glands of the large intestine represent merely furrows between adjacent elevations, and are not due to an active proliferation of cells at the base of the furrows, and hence a distinction may be drawn between the two, and be expressed by using the term intestinal glands for the depressions of the small intestine and intestinal follicles for those of the large intestine.

According to v. Nagy, whose description has been followed above, the glandular epithelium of the gastric glands begins to assume its differentiated form in different parts, *i.e.* cardiac and pyloric glands, towards the fifth month of development.

2. **Organ Formation—Œsophagus.**—The lengthening of the thoracic region of the trunk, which occurs with the growth and development of the heart and lungs, causes this portion of the alimentary tube to become greatly lengthened. Vacuoles appear in the epithelial lining, and coalesce to form the wide lumen.

Stomach.—As early as the fourth week, the foregut exhibits a fusiform enlargement in the region of the developing heart, which is the first evidence of the differentiation of the stomach: this enlargement takes the form first of an outgrowth on the dorsal border to form the fundus. Soon, however, as the diaphragm is being formed, the stomach passes into the abdomen, and its dorsal wall—the future greater curvature—begins to grow more rapidly than the ventral wall. As a result the whole organ becomes somewhat curved, and its inferior end is carried forwards from the posterior abdominal wall, giving rise to the curvature of the duodenum. The excessive growth of its posterior wall causes the stomach to turn over on to its right side, which now becomes posterior or dorsal. In this rotation the upper or cardiac portion moves to the left of the median plane, and the whole organ assumes an oblique direction across the abdomen Already, at the fifth or sixth week, the adult form of the stomach is clearly indicated.

This rotation of the stomach around its long axis, which is accompanied by a rotation of the lower end of the œsophagus, explains the asymmetrical position of the two vagi. In the adult

the left nerve is found on the front of the stomach, which was originally the left side of the organ; similarly, the right nerve lies on the back, which was originally the right side.

Intestines.—At first there is no separation into large and small intestines; the primitive canal simply forms a slender tube, with a convexity towards the umbilical orifice, through which the vitelline duct passes to the yolk sac. Later, the tube increases in length, and in embryos of 11 or 12 mm. and about five weeks old an outgrowth of the canal appears, which represents the future cæcum, and indicates the separation into large and small intestines. Growing longer, the intestine forms a large loop with the vitelline duct springing from its apex (Fig. 951), and the superior mesenteric artery running down between the layers of its mesentery. This loop passes outside the body of the embryo and lies for some time in the umbilical cord. As the abdominal cavity increases in size it retracts into the abdomen. This primary loop is known as the entero-colic loop, and from it are formed the intestine from the distal end of the duodenum to the left colic flexure. At the root of the loop, where the proximal and distal ends come to lie close to one another, lateral bendings of the intestine appear, the intestine proximal to the upper root bends over and forms a loop convex to the right,—the gastro-duodenal loop, supplied by a branch of the cœliac axis artery, and giving origin to the duodenum. The distal portion of the intestine, supplied by the inferior mesenteric artery, forms a loop on the posterior abdominal wall convex to the left (Fig. 951). There now takes place a change which entirely modifies the position of the parts—this is a rotation of the entero-colic loop, with its mesentery, around the superior mesenteric artery as an axis (Fig. 951). The result of this rotation is that the original right side of the loop of gut and mesentery becomes the left side; and the beginning of the large intestine is carried across the duodenum (Fig. 951), thus explaining the passage of the transverse colon in front of the second part of the duodenum in the adult. At the same time the cæcum comes to lie near the middle of the abdomen below the liver, a position in which it is found during the third month. Subsequently, it passes farther to the right; and finally, descending, comes to occupy its adult position (Fig. 952).

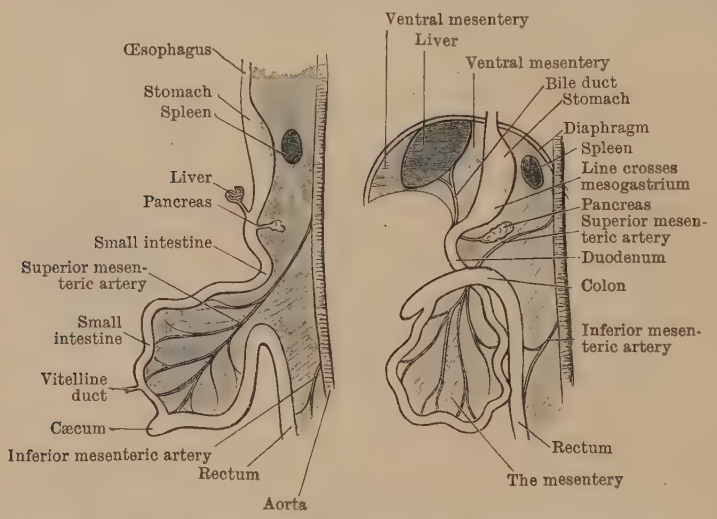

FIG. 951.—TWO DIAGRAMS TO ILLUSTRATE THE DEVELOPMENT OF THE INTESTINAL CANAL.

The figure to the right shows the rotation of the intestinal loop around the superior mesenteric artery. In both figures the parts are supposed to be viewed from the left side.

The small intestine continues to grow in length, and, as a result, is thrown into coils, which become more and more complex as the length increases, until the adult condition is attained. The terminal portion of the large bowel retains its position on the left side, and passes down to the anus.

Cæcum and Vermiform Process.—The cæcum appears at about the fifth week, as a small outgrowth of the wall of the primitive gut (midgut), not yet differentiated into small and large intestines. The outgrowth is of the same size throughout, and is practically equal to the intestine in diameter. About the eleventh week it increases very considerably in length (being equal to about five times the diameter of the small intestine, and thus being relatively as long as in the adult); but even at this early date the basal portion, for about one-fifth of its length, is quite as wide as the intestine, whilst the remaining four-fifths of the outgrowth—the future vermiform process—is only about one-half or one-third the diameter of the gut. Thus the distal portion of the outgrowth, which subsequently becomes the vermiform process, begins to lag behind even at this early period of its development.

The basal portion continues to expand with the gut; the distal part grows rapidly enough in length, but otherwise enlarges very slowly, so that, towards the end of fœtal life, the cæcum has attained a conical shape, the wider end joining the ascending colon, the narrow end tapering gradually and passing into the vermiform process. This form, known as the infantile type of cæcum, is retained for some time after birth, or even may (in 2 or 3 per cent of cases) persist throughout life.

As early as the sixth or seventh month of fœtal life the wall of the terminal portion of the small intestine adheres to the medial side of the cæcum for some distance below the ileo-cæcal orifice. This connexion, which is rendered more intimate by the passage of two folds of peritoneum, one on the front, the other on the back, between the two parts, profoundly modifies

the subsequent growth of the cæcum, and determines very largely its adult form. For, when the cæcum begins to expand, the medial aspect is prevented, by its connexion with the termination of the ileum, from enlarging as freely as the rest of the wall; in consequence of this the lateral part grows and expands much more rapidly, producing the lop-sided appearance already referred to, and soon comes to form the lowest part or fundus of the cæcum, and the greater part of its sac; whilst the original apex, with the vermiform process springing from it, anchored, as it were, to the end of the ileum, is thrust to one side, and finally lies on the medial and posterior aspect of the cæcum, a little way below, and usually posterior to, the end of the ileum.

The position of the cæcum varies at different periods of fœtal life. About the eleventh or twelfth week it lies immediately beneath the liver, and to the left of the median plane; it then gradually travels to the right, crossing the descending part of the duodenum, and is found lying on the right side, just beneath the liver, at the fourth month. From there it descends slowly to its adult position, which it usually approaches towards the end of fœtal life, but it may not actually reach it until some time after birth. An imperfect descent gives rise to the lumbar position of the cæcum, or an excess in this direction to the pelvic position (referred to on p. 1203).

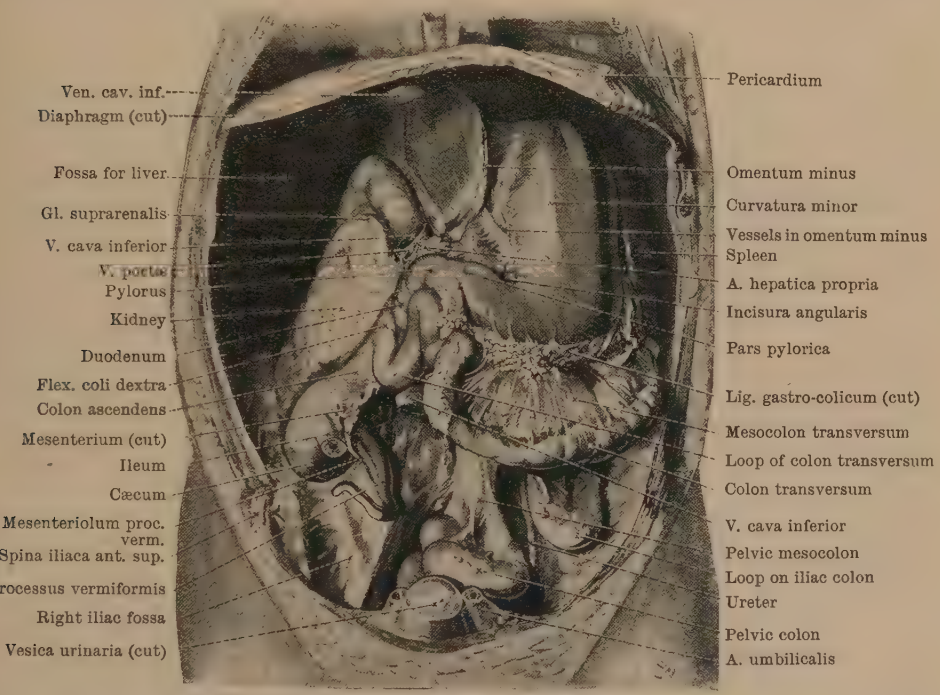

FIG. 952.—THE ABDOMINAL VISCERA IN THE NEWLY-BORN CHILD. The liver and the jejunum and ileum have been removed. The vertical stomach, the large supra-renal gland, the high position of the cæcum, and the whole arrangement of the large intestine are typical of the condition found at birth, and differ, as can be seen, largely from the adult condition.

Rectum.—The rectum and anal canal are formed from the posterior portion of the hindgut, and from the proctodæum.

The primitive closed cloacal portion of the hindgut becomes divided by a vertical septum into ventral and dorsal portions. The ventral, with the allantois growing from it, forms the sinus urogenitalis, the dorsal forms the rectum.

The proctodæum is separated from the rectum by the proctodæal membrane, but that membrane disappears, and thus the rectum comes to open on the surface.

A spindle-shaped enlargement of the terminal portion of the rectum is early formed, and persists until birth, and a smaller temporary enlargement is formed proximal to it. The wall of the distal swelling is thrown into numerous longitudinal ridges and folds from which the rectal columns are formed.

The rectum and anal canal at first form a single continuous straight tube, which passes downwards in front of the comparatively straight anterior surface of the sacrum to the anal orifice.

That is the condition which the parts present at birth. After birth, the bony pelvis undergoes great enlargement. The sacrum and coccyx become curved, and the antero-posterior diameter of the pelvis minor increases very considerably.

The urinary bladder and, in the female, the uterus—both organs at birth lying mainly in the abdomen—descend into the pelvis minor. The anal orifice appears to be moved further

forwards in the perineum, through the bending of the sacrum and coccyx, and the rectum is pushed back into the hollow of the sacrum. Hence the "flexura sacralis" is formed.

The "flexura perinealis" is formed by the junction of the curved rectum with the straight vertical or backwardly directed passage formed by the intestine as it passes through the tissues of the pelvic floor.

The increase in the thickness of the pelvic floor gives to the anal canal the length which it attains in the adult.

"Atresia ani" may be persistence of a proctodæal membrane, but in many cases there is imperfect development of all the lower portion of the rectum.

Development of the Peritoneum.

At first the primitive alimentary canal is suspended from the dorsal wall of the embryo, along the median plane, by a **simple dorsal mesentery**, which extends along the whole length of the tube, and is common to all its divisions—a condition found in the adult stage of many reptiles. There is also present, in the upper part of the cavity, after the stomach and liver descend into the abdomen, a **ventral mesentery** (Fig. 951), which connects the stomach and duodenum to the liver, and, passing on, connects the front of the liver to the anterior abdominal wall and diaphragm. The portion of this ventral mesentery, between the stomach and liver, becomes the lesser omentum; its anterior portion, between the liver and the abdominal wall, forms the falciform ligament (Fig. 951); and, in its inferior margin, the umbilical vein runs from the umbilicus to the liver.

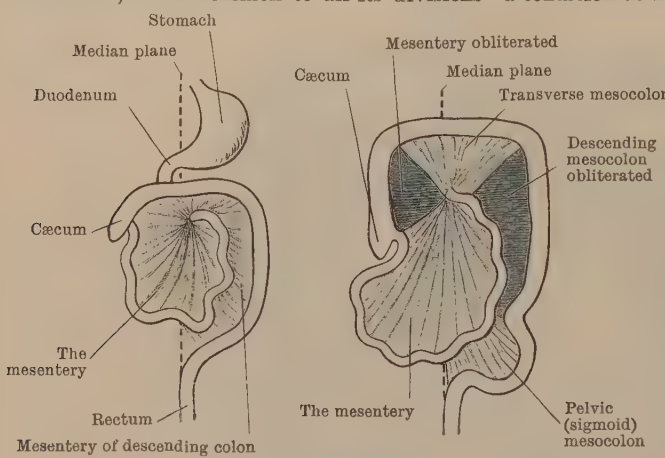

Fig. 953.—Two Diagrams to illustrate the Development of the Mesenteries.

In the first figure the rotation of the intestinal loop and the continuous primitive mesentery is shown. In the second figure (to the right), which shows a more advanced stage, the portions of the primitive mesentery (going to the ascending and descending colons) which disappear, through their adhesion to the posterior abdominal wall, are shaded dark; the portions which persist are lightly shaded.

The portion of the dorsal mesentery lying behind the stomach is known as the **mesogastrium**. At first it is relatively short; but with the growth of the posterior wall of the stomach, and the turning of that organ over on its right side, the mesogastrium becomes elongated, and is folded on itself, forming more or less of a pouch, directed downwards and to the left. The wall of this pouch becomes in part the greater omentum, and the cavity enclosed by it forms the greater part of the omental bursa. In the rotation of the stomach and the accompanying passage of the lesser omentum from an antero-posterior to a more or less transverse direction, a portion of the cavity of the abdomen is, as it were, caught in behind the stomach and lesser omentum. This portion of the cavity becomes the upper part (vestibule) of the omental bursa, and at first it communicates with the general cavity by a wide opening to the right of the lesser omentum; but the growth of the liver, encroaching upon the opening, and other causes, reduce it to a relatively small size, and it forms the **foramen epiploicum** in the adult.

The "recessus superior" of the bursa omentalis has a complicated origin. It represents the right of two pocket-like recesses, a right and a left, which are formed very early in the dorsal wall of the cœlom.

These two recesses are narrow and horizontal slits, which burrow into the dorsal wall, and turn upwards by the side of the œsophagus. They are termed the "pneumato-enteric recesses." The left one disappears entirely. The apex of the right one remains occasionally as the "bursa infra-cardiaca" of the right lung, and is cut off by the diaphragm from the lower portion, which is the origin of the recessus superior.

The **greater omentum** is, as pointed out above, a bag-like growth of the lower part of the mesogastrium, which passes downwards and to the left in front of the transverse colon. As shown in Fig. 954, A and B, it is first entirely unconnected with the transverse colon and mesocolon; but about the third or fourth month it becomes united to both, and the adult condition is established (Fig. 954 C).

It would appear that the growth of the inferior part of the omental bursa, and of the greater omentum, is primarily due to a proliferation of the cells over a limited area of the mesogastrium, and a resulting folding of this layer downwards and to the left.

In the upper part of the mesogastrium the **spleen** is developed, and the portion of this fold

which intervenes between the stomach and spleen forms the gastro-lienal ligament, whilst the part behind the spleen becomes the lieno-renal ligament.

Of the primitive mesentery, the portion connected with the stomach—the mesogastrium—becomes modified in the manner just described. The next division—the mesoduodenum—disappears completely, owing to the turning over of the duodenal loop on to its right side, and its subsequent adhesion to the posterior abdominal wall, accompanied by the absorption of its mesentery. The mesenteries of the small and large intestine are continuous at first (Fig. 951). When the rotation of the intestinal loop takes place around the superior mesenteric artery (see above), the beginning of the large intestine, with its mesentery, is carried to the right across the duodenum, and a fan-shaped portion of the general mesentery, lying within the concavity of the loop, is partially cut off; this, later on, forms the mesentery proper in the adult. At first it is continuous by its right border with the mesentery of the ascending colon, a part of the primitive mesentery (which is similarly continued into the mesentery of the transverse, descending, iliac, and pelvic colons).

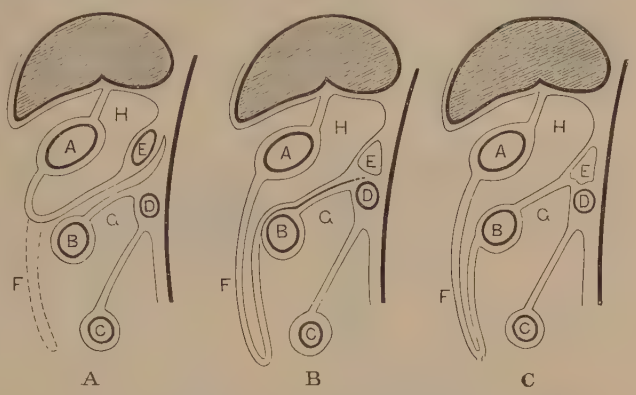

Fig. 954.—Diagrams to illustrate the Development of the Greater Omentum. (After Hertwig.)

A, shows the beginning of the greater omentum and its independence of the transverse mesocolon; in B, the two come in contact; and in C, they have fused along the line of contact. (According to Lockwood, the two layers of the fold shown in A, running in between the greater omentum and transverse mesocolon, instead of fusing, as shown in B, are drawn out—unfolded—producing the condition shown in C.) A, stomach; B, transverse colon; C, small intestine; D, duodenum; E, pancreas; F, greater omentum; G, placed in great sac; H, in omental bursa.

Subsequently, as shown by the darkly shaded parts in Fig. 953, the back of the mesenteries of the ascending, descending, and iliac portions of the colon adheres to the posterior abdominal wall, and these mesenteries become lost; whilst the mesenteries of the transverse and pelvic portions of the colon remain free, and persist in the adult.

At the same time, the mesentery proper (which was at first attached only at its narrow neck, between the duodenum and transverse colon, and below this was continuous on the right with the ascending mesocolon) now acquires a new attachment to the posterior abdominal wall through the absorption of the ascending mesocolon (Fig. 953), and the adult condition is attained.

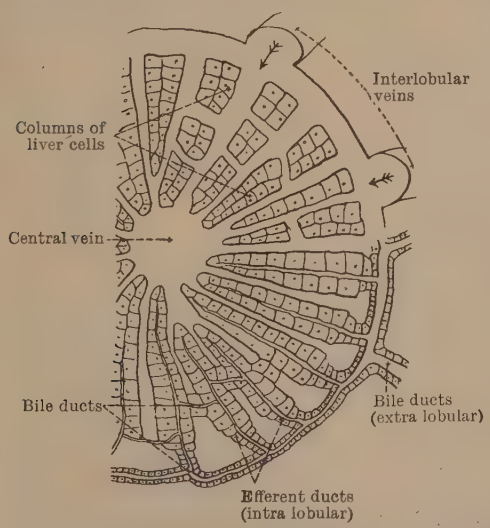

Fig. 955.—Diagram to illustrate the Structure of a Liver Lobule.

Development of the Liver and Pancreas.

The glandular tissue of the liver and pancreas, and the epithelial linings of the ducts of these organs, including the gall-bladder and cystic duct, are formed from protrusions of the endothelial wall of the foregut, below the stomach. The connective tissue framework of the glands is formed from the mesodermic tissue into which the protrusions grow.

The process of formation is as follows:—

1. **Liver.**—A longitudinal groove appears on the interior of the ventral wall of the foregut, close to its union with the midgut, at about the third week. This groove appears on the external surface of the gut as a projection, which rapidly increases in size and grows forwards and upwards towards the lower part of the septum transversum. This septum is a mass of mesodermic tissue which lies in front of the foregut, just below the heart, and which is attached to the anterior and side walls of the trunk. It conveys the umbilical and vitelline veins as they pass to the sinus venosus.

The liver bud grows into the lower (caudal) portion of the septum transversum, and sends out strands of cells termed trabeculæ, which come into contact with the vessels in the septum, and enclose them.

By the growth of capillary vessels, from the vitelline and umbilical veins, and of the

trabeculæ, a spongy network is produced, the framework of which is formed by branching and anastomosing trabeculæ, while the spaces of the network represent portions of the lumen of the vessels, and are filled with blood. This form of vascular network is known as a "sinusoidal circulation."

The trabeculæ become hollowed out, and are reduced in size, so that eventually a minute channel is formed in the centre of each of them, surrounded by a single layer of cells. The lumen of the channel forms a bile capillary, and the cells surrounding it form the secreting cells of the liver lobule.

The bile capillaries of adjacent trabeculæ meet and unite, and converging together constitute the bile ducts within the liver. Adjacent trabeculæ become arranged into the form of a lobule, each with a vascular channel in its interior, which communicates with the vascular network in the surface of the lobule by capillary intervals between adjacent trabeculæ.

The central vein becomes a tributary of a hepatic vein, and the capillary network becomes the terminal distribution of branches of the portal vein.

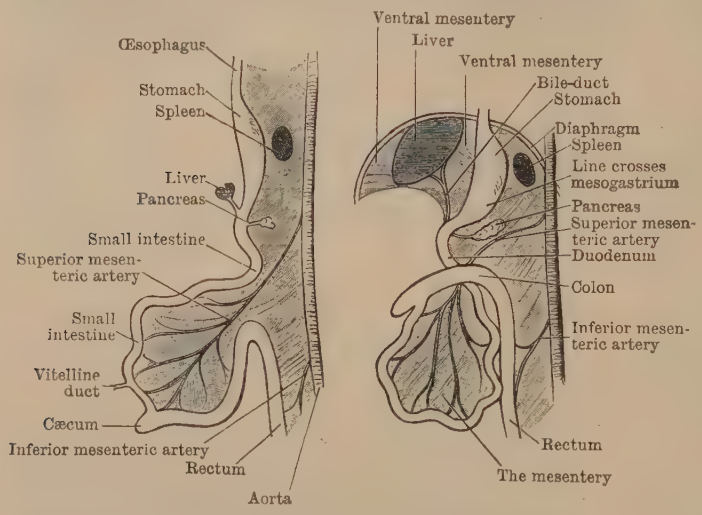

FIG. 956.—TWO DIAGRAMS TO ILLUSTRATE THE DEVELOPMENT OF THE INTESTINAL CANAL.

The figure to the right shows the rotation of the intestinal loop around the superior mesenteric artery. In both figures the parts are supposed to be viewed from the left side.

The proximal portion of the original hollow diverticulum becomes the bile duct, and the gall-bladder and cystic duct are formed by an evagination from it.

As the liver increases in size, it begins to project down from the inferior part of the septum transversum into the ventral mesentery, so that now, instead of being situated within the septum, it looks like an appendage of its inferior surface. In other words, the septum begins to differentiate into two parts—an inferior, the liver, and a superior, which constitutes the greater portion of the diaphragm, both of these having been at first one continuous mass. In the course of development the separation of the two becomes more marked, and finally is complete everywhere except at the coronary and lateral ligaments behind, and at the falciform ligament in front, where they are still connected.

As the liver separates off from the future diaphragm, and descends into the abdomen, it lies between the layers of the **ventral mesentery**—a fold which connects the stomach and duodenum with the anterior abdominal wall. This is divided by the liver into two parts—a lower, stretching from the front (lesser curvature) of the stomach to the liver, which becomes the lesser omentum; and an upper, stretching from the liver to the diaphragm and anterior wall of the abdomen, which forms the falciform ligament.

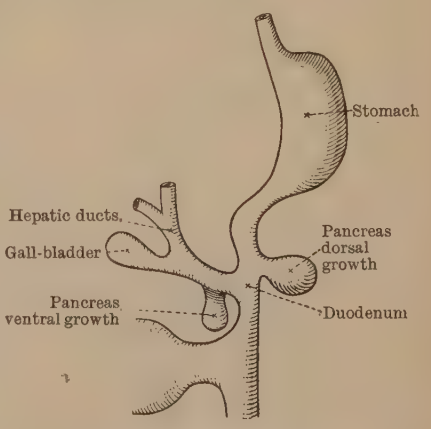

FIG. 957.—DIAGRAM OF THE ORIGIN OF THE LIVER AND PANCREAS.

2. **Pancreas.**—The pancreas is developed at a very early period in man (being present in embryos of 5 mm.) from two outgrowths from the alimentary canal, a dorsal and a ventral.

The dorsal rudiment is an outgrowth from the dorsal aspect of the intestine, anterior to the origin of the hepatic outgrowth. The ventral rudiment grows at a later stage from the root of the hepatic bud in the form of two ventral offshoots, one on either side. That on the left side, however, soon disappears.

Through the rotation of the duodenum around its long axis, the dorsal and ventral rudiments approach one another and become fused, and their ducts open on the left side of the duodenum. The connecting stalk between the ventral rudiment and the hepatic bud becomes the main duct of the pancreas, while the connexion of the dorsal outgrowth with the duodenum remains as the accessory pancreatic duct. In embryos of the fifth week, a large dorsal pancreatic rudiment is present, and also a smaller ventral rudiment, which opens into the duodenum in common with

the bile duct, and lies on the right of the vena portæ. In the sixth week, these two rudiments meet and unite with one another, forming a long slender glandular mass which passes backwards within the dorsal mesogastrium (mesoduodenum), between the vertebral column and the greater curvature of the stomach. The pancreas, so formed, follows the changes which occur in the position of the stomach and of the dorsal mesogastrium. Consequently its free dorsal extremity comes to be directed to the left, while the right extremity or head is included within the hollow of the curve formed by the duodenum. At first, it possesses a dorsal mesentery, a part of the dorsal mesogastrium, but from the fifth month this disappears, coincidently with the rotation of the gland into the transverse axis of the body.

The lower part of the head, the body and tail of the gland arise from the ventral element, and the upper part of the head arises from the dorsal bud.

The primary diverticula give off buds, lined with cylindrical epithelium, and these in turn give off other buds, and the process goes on until the mass of the gland is formed.

The islets of Langerhans are formed at a very early stage, from the entodermal lining cells of the branching diverticula which form the gland acini.

THE URO-GENITAL SYSTEM.

By A. Francis Dixon.

THE URINARY ORGANS.

The **kidneys**, or glands which secrete the urine, are a pair of almost symmetrically placed organs, situated in the posterior part of the abdominal cavity, one on each side of the lower movable portion of the vertebral column. The fluid, or urine, secreted by the kidneys is received into the upper expanded portions of a pair of long tubes, the **ureters**, and by them it is conducted to the **urinary bladder**, which is placed within the lesser pelvic cavity. From the bladder the urine is passed, during micturition, along a passage called the **urethra** to the exterior. In the male the urethra is a relatively long passage, and traverses the prostate gland and the whole length of the penis; in the female it is a short tube, and opens on the surface just above the vaginal orifice.

THE KIDNEYS (RENES).

The **kidney**, when removed from a fresh subject, presents a bean-shaped contour. It is of a dark brown-red colour, and is surrounded by a thin glistening capsule, the **tunica fibrosa**, which gives to the whole organ a uniformly smooth surface. The kidney is not a solid body, but contains a cavity called the **renal sinus**, the opening into which, termed the **hilum**, is situated on the medial and anterior part of the organ. Each kidney measures about $4\frac{1}{2}$ inches in length, 2 inches in width, and about $1\frac{1}{4}$ inches in thickness, and is placed so that its long axis is nearly vertical. The weight of the adult kidney is about $4\frac{1}{2}$ ounces. In the freshly removed kidney the superior and inferior ends are smoothly rounded, and the **superior end** is usually a little more bulky than the **inferior end**. The **lateral border**, which is opposite the hilum, is rounded and convex, while the **medial border**, on which the hilum is placed, is concave from above downwards. These two borders separate the **anterior surface** from the **posterior surface** of the kidney.

The *capsule*, which envelops the whole organ, divides in the region of the hilum into two layers, one of which is continued over the lips of the hilum into the interior of the kidney, and lines the walls of the renal sinus. The other layer is prolonged to form a tubular sheath for the vessels and nerves of the kidney before they pass through the hilum to enter the sinus, within which they break up into branches. These branches, piercing the wall of the sinus, enter the substance of the kidney. The upper expanded portion of the ureter leaves the sinus, through the hilum, in company with the blood-vessels and nerves.

Position of the Kidneys.—The precise level of the kidney in the abdominal cavity is subject to a considerable amount of variation, and, further, it is usual to find a difference in the level of the right and left kidney in the same individual. Most frequently the left kidney is on a somewhat higher level than the right, but in many cases the kidneys are found to occupy the same level, or, the more usual condition being reversed, the right kidney is a little higher than the left.

If a line is drawn round the body at the level of the lowest part of the thoracic wall, the whole, or almost the whole, of the left kidney will be found to lie above the level of the subcostal plane so determined. It is, therefore, situated in the subcostal zone of the abdominal cavity. The right kidney, however, although it lies for the most part in the subcostal zone, usually projects at its inferior part somewhat below the subcostal plane, and hence lies to some extent in the umbilical zone. It is often stated that the kidneys are placed on a somewhat lower level in the female than in the male subject.

By far the greater part, usually two-thirds or more, of the kidney lies to the medial side of a line drawn vertically upwards through the middle point of the inguinal ligament.

The posterior aspect of the kidney is closely applied against the muscles attached to the bodies of the last thoracic and upper three lumbar vertebræ, and is placed in front of the last rib and of the transverse processes of the upper three

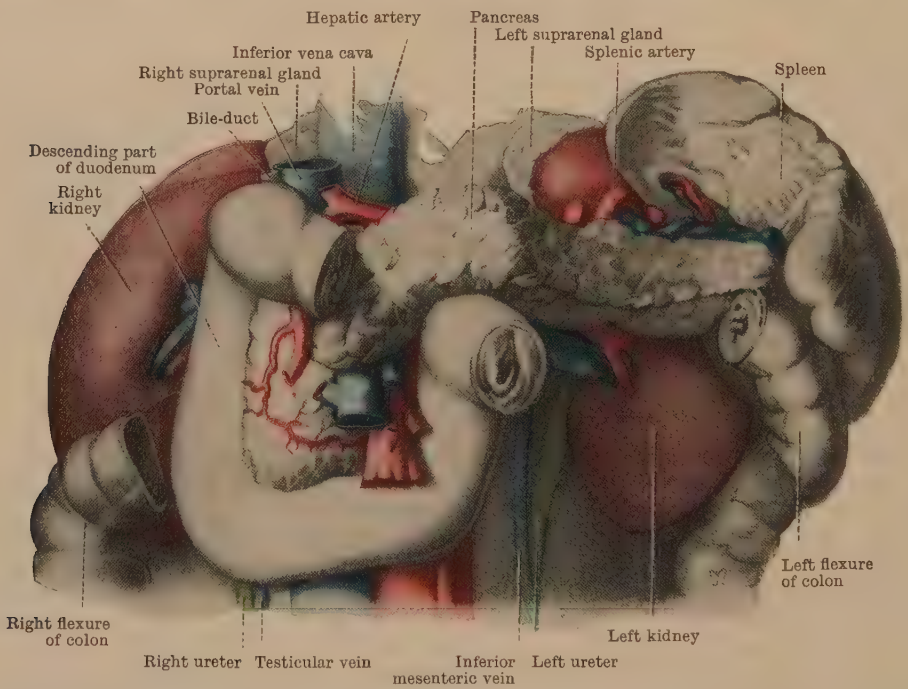

FIG. 958.—DISSECTION TO SHOW THE RELATIONSHIPS OF THE KIDNEYS. The greater part of the stomach has been removed by an incision made close to the pylorus. The transverse colon has been taken away, and the small intestine has been cut across close to the duodeno-jejunal flexure.
A model prepared by the late Professor Birmingham has been made use of in this drawing.

lumbar vertebræ. In some cases, more frequently on the left side of the body, the eleventh rib also lies behind the upper part of the kidney. The relationship of the kidney to the lower two ribs is, however, very inconstant, owing partly to the great variability in size and inclination of those bones.

The inferior end of the kidney is usually situated from $1\frac{1}{4}$ to 2 inches above the highest part of the crest of the ilium; the interval between the kidney and the ilium being usually greater on the left side of the body.

Occasionally the inferior end of the kidney lies on the same level as, or only a short distance above, the iliac crest; this condition is sometimes due to the crest rising to a higher level than usual, the kidney occupying its normal position in relation to the vertebral column. It is important to remember that during life the kidney moves upwards and downwards, following the respiratory movements of the part of the diaphragm against which it rests.

The long axis of each kidney is somewhat oblique, its superior end approaching nearer to the median plane than the inferior. The surface of the kidney which is applied against the muscles forming the posterior wall of the abdomen looks,

as a whole, backwards and medially, and that which projects into the abdominal cavity looks forwards and laterally. Hence it happens that the lateral border lies on a more posterior plane than the medial border. The kidney is rotated in this manner on its long axis to such a degree that the medial margin and hilum are scarcely visible from behind, and only a limited view of the lateral border can be obtained from the front (Figs. 958 and 959).

The kidneys are placed behind the peritoneum, and project into the posterior part of the abdominal cavity. Each is surrounded by a considerable amount of loose tissue, often loaded with fat; the fatty tissue, or **capsula adiposa**, being present in greater quantity round the margins of the kidney, and only to a less extent in front of and behind the organ. The renal vessels and nerves lie in this fat before they enter the kidney, and the adipose tissue is continued, along with the vessels, through the hilum into the renal sinus, where it fills up all the space unoccupied by the vessels and nerves.

Embedded in the soft fatty tissue surrounding the kidney is a layer of fibrous

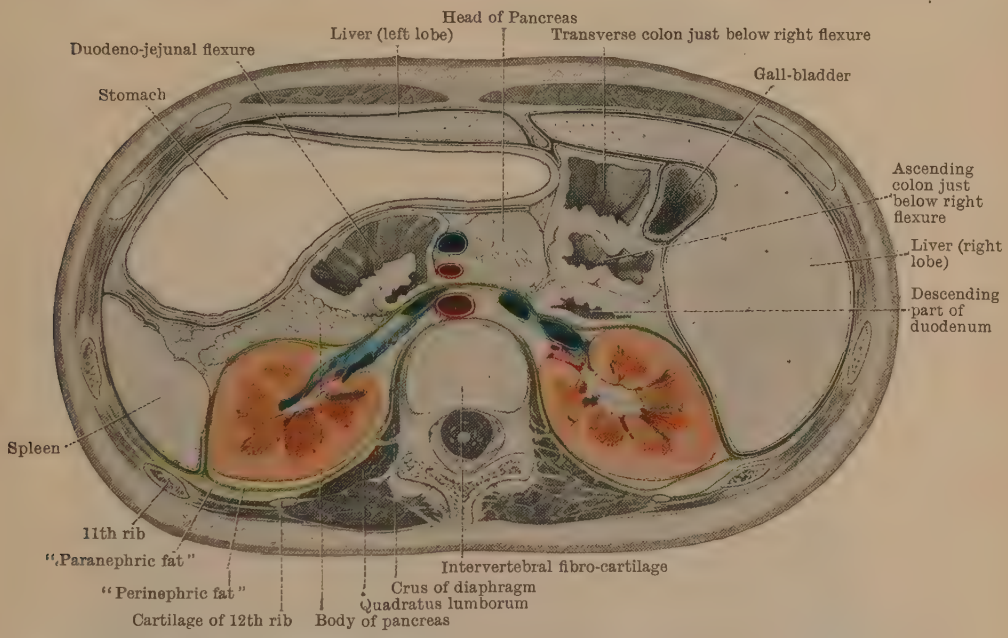

FIG. 959.—TRANSVERSE SECTION THROUGH THE BODY OF A CHILD. The position and relationships of the kidneys are well seen, and the arrangement of the fascia renalis is indicated. The fascia is coloured green.

tissue to which the term **renal fascia** is applied. This fascia surrounds the kidney and a considerable amount of its fatty capsule in the form of a loose sheath, in which may be distinguished anterior and posterior walls. The sheath is open inferiorly and medially, but closed above and to the lateral side of the kidney by the apposition of its walls. Laterally, the anterior and posterior walls of the sheath come into contact and are connected with the retro-peritoneal tissue. Medially they remain distinct, and the anterior wall is continued across the median plane, in front of the renal vessels and the aorta, to join the corresponding layer of the opposite side, while the posterior wall fuses with the fascia covering the psoas and quadratus lumborum muscles. Inferiorly, below the level of the kidney, the anterior and posterior layers of the renal fascia remain separate, and can be traced downwards into the iliac fossa. Above the level of the kidney and the suprarenal gland the layers of the renal fascia unite and join the fascia covering the diaphragm. The term "perinephric fat" is applied to the loose fatty tissue enclosed along with the kidney within the sheath of renal fascia, and "paranephric fat" is used to denote the tissue outside the renal fascia (Fig. 959). The fibrous capsule of the kidney is joined to the loose sheath formed by the renal fascia by numerous connective tissue strands. These traverse the peri-

nephric fat and undoubtedly assist in fixing the kidney in its place. The paranephric fat is present in greatest quantity behind the inferior part of the kidney, and in this position the layer of fibrous tissue, separating the two masses of fat and forming the posterior layer of the sheath of renal fascia, is usually well marked.

Fixation of the Kidney.—The kidney is not held in its place by any distinct ligaments, or special folds of peritoneum, but its fixation depends, to a large extent, on the pressure and counter-pressure which is exerted upon it by neighbouring structures, and on its connexions with the **renal fascia** above described.

Posterior Relations and the Posterior Surface of the Kidney.—The muscles of the posterior abdominal wall on which the kidney rests are the psoas major, the quadratus lumborum, the diaphragm and the tendon of the transversus abdominis. The abdominal surfaces of these muscles do not lie on the same plane, but slope towards one another, and thus the bed on which the kidney rests is not flat. When but little fat is present, the posterior aspect of the kidney adapts itself to the

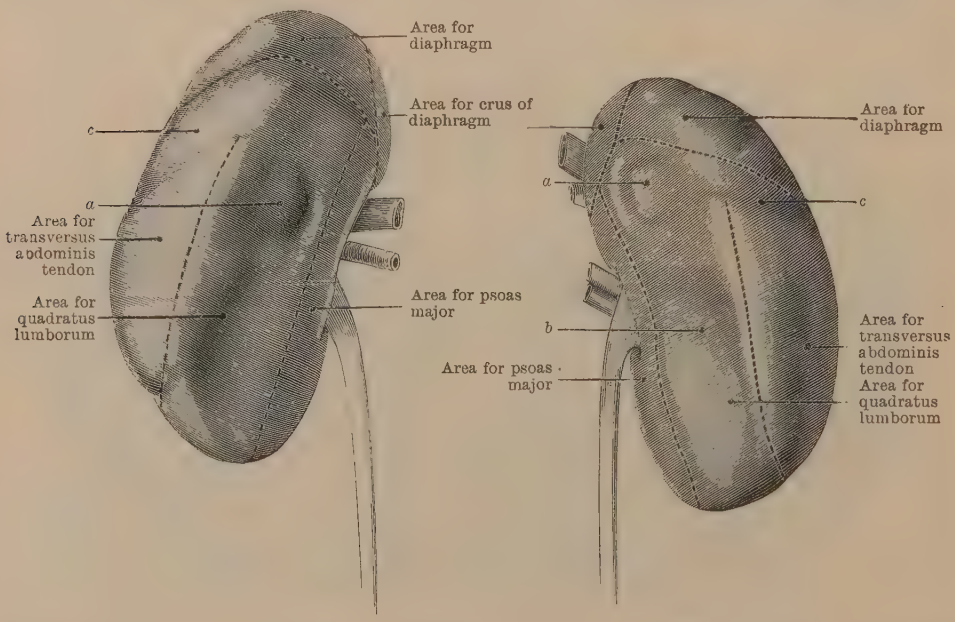

FIG. 960.—THE POSTERIOR ASPECT OF THE KIDNEYS. The dotted lines mark out the areas in contact with the various muscles forming the posterior abdominal wall.

a and *b*. Depressions corresponding to the transverse processes of the first and second lumbar vertebræ.
c. Depression corresponding to the twelfth rib.

inequalities of the surface against which it is placed, and so we may find on a kidney which has been carefully fixed and hardened before it has been disturbed, areas marked off for the different planes of these muscles. When such a kidney is in position, slight ridges or elevations separating these areas correspond to the angles along which the different muscular planes meet. These ridges can be observed in the hardened kidney, after its removal from the body, but usually they are not sharply defined, the angles between the muscular planes being very obtuse.

A kidney removed from the body after having been hardened *in situ* (Fig. 960) presents an area along the medial part of its posterior surface adapted to the anterior aspect of the psoas major muscle. This part of the posterior surface looks medially and slightly posteriorly. More laterally there is a larger area which rests against the quadratus lumborum and looks more directly backwards. These two areas are separated by a rounded ridge which fits into the angle between the muscles mentioned. Beyond the area in contact with the quadratus lumborum is the thick lateral border of the kidney, which rests for the most part on the tendon of the transversus abdominis and on the diaphragm.

Towards the superior end of the kidney the posterior surface slopes somewhat

forwards and rests upon the diaphragm. Indeed the superior part of the kidney is, as a whole, bent slightly forwards, following that part of the arch of the diaphragm on which it rests, and thus a narrow interval is left, in which the pleural cavity passes down behind the superior end of the kidney. This relationship of the pleural cavity to the kidney is of great importance in connexion with surgical operations performed through an incision in the lumbar region. The portions of the diaphragm to which the kidney is applied are the crus and the parts arising from the last rib and lumbo-costal arches.

The anterior divisions of the last thoracic nerve and the ilio-hypogastric and ilio-inguinal branches of the first lumbar nerves pass downwards and laterally in close relationship to the posterior aspect of the kidney.

The posterior relationships of the kidney are well seen in Figs. 959, 842.

In addition to these surfaces, or "facets," for the muscles with which it is in contact, the posterior aspect or lateral border of the kidney often shows a groove for the last rib, another for

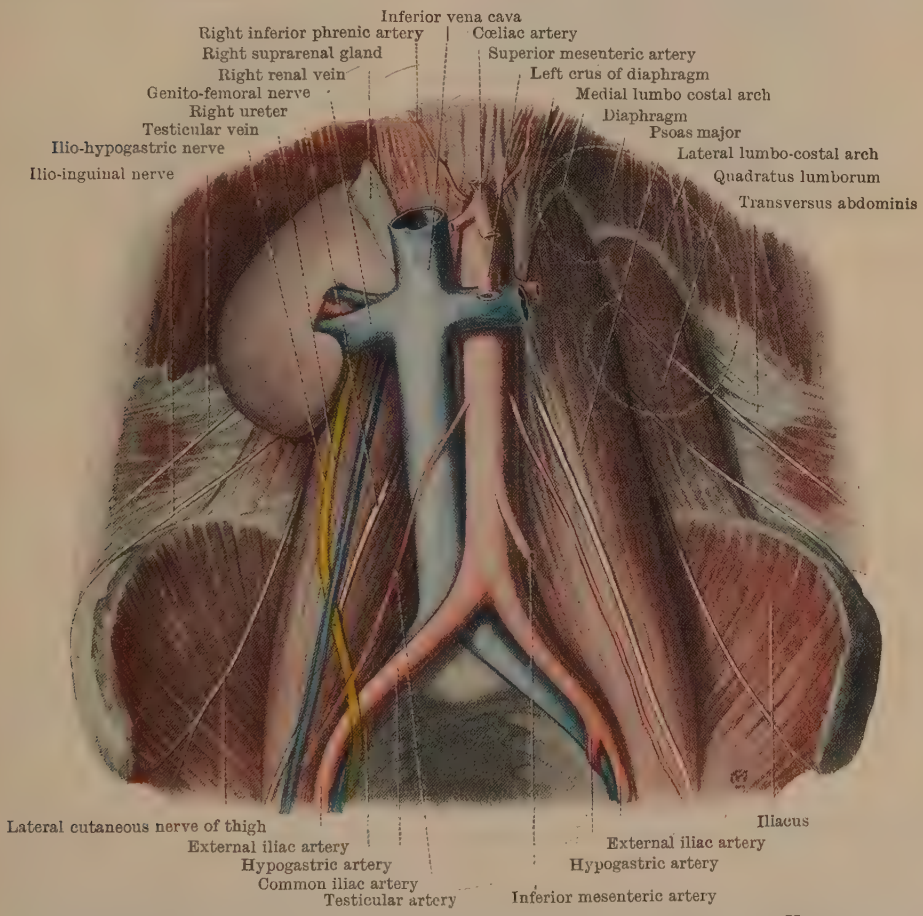

FIG. 961.—DISSECTION TO SHOW THE RELATIONSHIPS OF THE KIDNEY AND OF THE URETER TO THE POSTERIOR ABDOMINAL WALL. The dotted outline indicates the position of the left kidney.

the lateral lumbo-costal arch, and two or three depressions for the tips of the transverse processes of the upper two or three lumbar vertebræ. In some cases also faint narrow grooves are to be seen for the nerves which pass downwards and laterally between the kidney and quadratus lumborum.

It is probable that some at least of the depressions on the posterior aspect of the kidney are produced after death, and are caused by the weight of the other abdominal organs pressing the kidney backwards against the more resisting structures of the abdominal wall, at a time when the muscles behind the kidney have become flaccid. When much fat is present the posterior aspect of the kidney is more uniformly convex.

The **lateral border** in its middle and inferior part is rather a surface than a border, and looks for the most part directly backwards. It rests on the diaphragm

and on the anterior surface of the tendon of the transversus abdominis, to the lateral side of the quadratus lumborum muscle. The lateral border is narrowest above, and widest just below its middle point, corresponding to the greater thickness of the kidney at this level.

In many ways it would be more satisfactory to apply the term **facies muscularis** collectively to the areas above described as "posterior surface" and "lateral border"; in like manner the term **facies visceralis** might be suitably applied to the so-called anterior surface of the organ. The edge separating the visceral from the muscular surface is the actual lateral edge, or border, of the kidney.

Anterior Relations and the Anterior Surface of the Kidney.—The anterior relations of the kidneys not only differ on the two sides of the body, but also many of the structures related to the anterior surface of each kidney undergo frequent

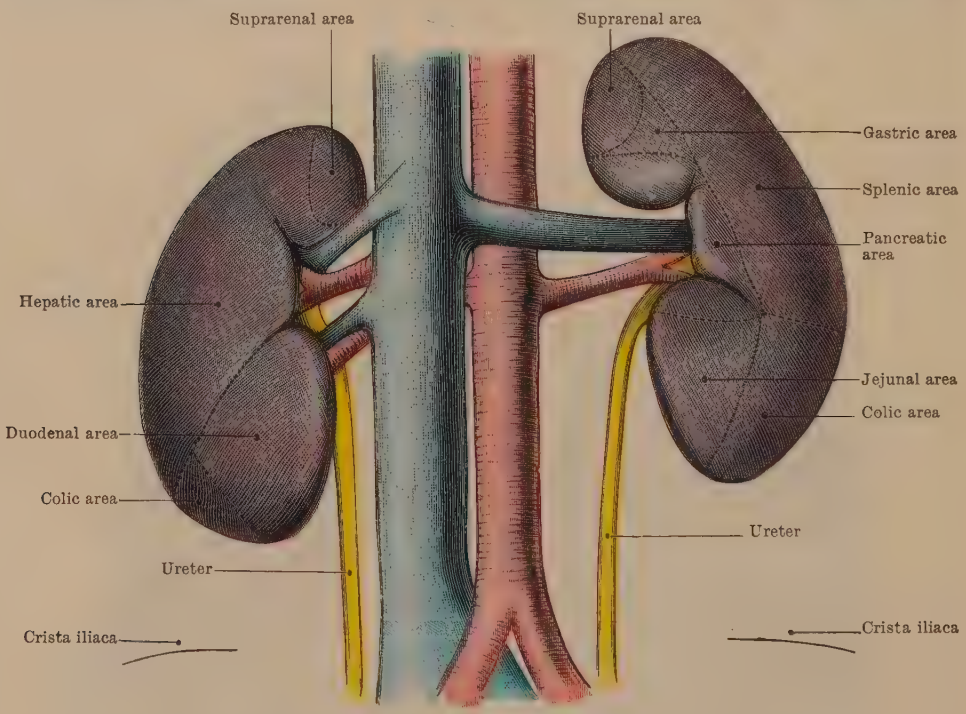

FIG. 962.—ANTERIOR ASPECT OF THE KIDNEYS AND GREAT VESSELS. The drawing was made, before removal of the organs, from a specimen in which the viscera had been hardened *in situ*. The dotted lines mark out the areas which were in contact with the various other abdominal viscera.

changes in position during life. Hence it is not possible to give more than a general account of the anterior relationships of the kidneys.

Right Kidney.—A small area on the superior part of the anterior surface of the right kidney is in relation to the corresponding suprarenal gland (Fig. 962). The rest of the superior part of the anterior surface is in contact with the visceral surface of the liver, which is often hollowed out to form a fossa for the kidney. The suprarenal gland is bound to the kidney by connective tissue, while the part of the kidney in relation to the liver is, like the liver itself, covered by peritoneum, and thus the two organs, although closely applied, are really separated by a part of the general peritoneal cavity. Immediately anterior to the inferior end of the right kidney are usually found two parts of the alimentary canal—namely, the descending part of the duodenum and the right flexure of the colon, or the commencement of the transverse colon. The part of the kidney related to the duodenum lies to the medial side of the area which touches the colon, but the exact amount of the kidney in contact with each of these two parts of intestine varies much in different subjects. Frequently the colon and the kidney are both covered

by peritoneum where they are in contact, but the duodenum is bound down to the kidney by connective tissue. In addition to the structures mentioned, some portion of the ileum, or of the jejunum, is often found in contact with a small part of the right kidney near its inferior end.

In some cases the peritoneal membrane does not cover the whole of the surface in contact with the liver, and then the superior part of the hepatic area of the kidney is, like the anterior aspect of the suprarenal gland, bound by connective tissue to the "uncovered" area on the posterior aspect of the liver.

Left Kidney.—The extreme superior and medial part of the anterior aspect of the left kidney is united by connective tissue to the lower part of the left suprarenal gland, and the area immediately below this is in contact with the stomach and the pancreas. The pancreas, like the suprarenal gland, is bound down to the kidney by connective tissue, but the stomach is separated from the area with which it is in apposition by a portion of the omental bursa. The area in actual contact with the stomach is a small somewhat triangular district situated above the level at which the pancreas is related to the kidney. The superior and lateral part of the anterior aspect of the kidney is related to the spleen, the two organs being separated by a portion of the general peritoneal cavity, except along the area where spleen and kidney are connected by the lieno-renal ligament. The anterior surface of the inferior end of the left kidney is related, towards the medial side, to a part of the jejunum, and, towards the lateral side, to the left flexure of the colon or to a part of the descending portion of the colon. In most cases, however, the colon lies against the posterior abdominal wall to the lateral side rather than on the anterior surface of the left kidney.

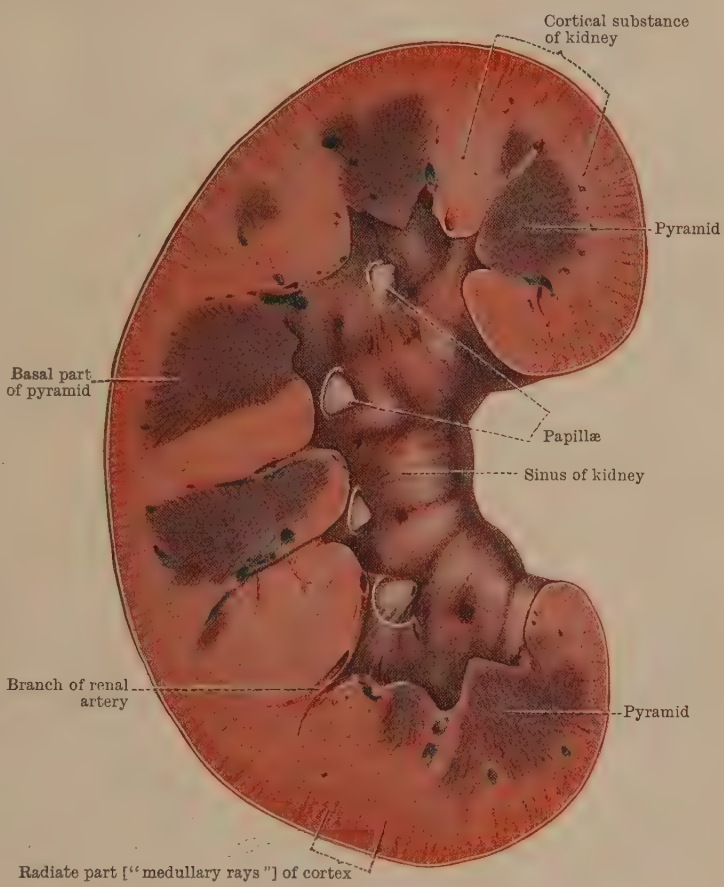

FIG. 963.—LONGITUDINAL SECTION THROUGH THE KIDNEY.

The vessels and fat have been removed to give a view of the wall of the kidney sinus. The points where the vessels enter the kidney substance are seen as holes in the sinus wall.

The right and left colic arteries, or their branches, as they pass laterally to reach the colon, are often related to the anterior aspects of the corresponding kidneys. The splenic vessels pass laterally in front of the left kidney (Fig. 958).

The anterior surface of a kidney which has been hardened *in situ* is, like the posterior surface, not uniformly rounded, but marked by a series of impressions corresponding to the different structures which lie in contact with it. In the case

of each kidney, the most prominent region on the anterior surface lies below the level of the middle of the kidney, and corresponds to the thickest part of the organ. From this prominence on the anterior surface a series of more or less flattened planes slope away towards the borders of the kidney. These flattened areas are impressions formed by the viscera which lie against the anterior surface of the kidney.

In the case of the **right kidney**, three areas or impressions can usually be distinguished on the anterior surface. One occupies the whole of the upper part of the organ, and is known as the **hepatic area**; another, the **colic area**, stretches from the most prominent point to the inferior end of the kidney, and is related to the colon; while the third or **duodenal area** extends along the medial margin, below the hilum, and is in contact with the second part of the duodenum (Fig. 962). The relative sizes of these three areas vary much in different specimens.

On the **left kidney**, also, three more or less defined, flattened areas slope towards the borders of the organ from the most prominent part of the anterior surface. One of these, on the superior and lateral part of the kidney, is the **splenic area**; another, extending downwards to the lower end of the kidney, is for the jejunum, or for the jejunum and colon; the third, above and in the region of the hilum, is called the **gastric area**, and corresponds to the position of the overlying stomach. Only a small portion of this area is in direct contact with the stomach, since the pancreas and a part of the suprarenal gland intervene between the stomach and the kidney (Fig. 958).

It is common to find the left kidney thicker and less flattened antero-posteriorly than the right, the impressions, or "facets," upon its surface being at the same time better marked. With this probably is to be associated the fact that *loose* or *floating kidney* is more rarely met with on the left than on the right side of the body.

Extremities of the Kidney.—The kidney, fixed and hardened *in situ*, is usually more pointed at its *inferior* than at its *superior* end. The latter is wider from side to side, and often somewhat flattened from before backwards. The superior end of the kidney is bent somewhat forwards and rests upon the diaphragm, which separates it, as explained above, from the inferior part of the pleural cavity.

Sinus Renalis.—The **sinus of the kidney** (Fig. 963), into which the hilum opens, is a narrow space, having its long axis corresponding to that of the kidney. The thick walls of the sinus cavity are formed by the substance of the kidney, and are lined by a part of the fibrous kidney capsule which enters the sinus over the lips of the hilum. The floor of the sinus is not even, but presents a series of small projecting conical elevations called **renal papillæ**, which vary from six to fifteen in number. Radiating from each papilla are a number of somewhat raised bars, or ridges, of kidney substance, separated by depressed areas. The blood-vessels and nerves enter and leave the kidney by piercing the wall of the sinus where it is formed by these little depressed areas. The summit of each renal papilla is pierced by a number of minute openings called **foramina papillaria**, which are the terminal apertures of the secreting tubules of which the kidney is mainly composed. These openings all lie close together, and give rise to the so-called **area cribrosa** upon the apex of the renal papilla. The urine secreted by the kidney escapes through the foramina papillaria into the subdivisions (calyces) of the ureter or kidney duct.

Kidney in Section.—Sections through the kidney (Figs. 963 and 965) show that it is composed to a large extent of a number of conical masses, known as **renal pyramids**. These together constitute the **medullary substance** of the kidney, and are arranged with their bases directed towards the surface, and their apices projecting into the renal sinus, where they form the renal papillæ already mentioned. The pyramids are more numerous than the papillæ, two or three usually ending in each papilla in the middle part of the kidney, and sometimes as many as six or more in each papilla near the superior and inferior ends of the organ. The bases of the pyramids do not reach the surface of the kidney, but are separated from it by a layer called the **cortical substance** of the kidney. The cortical substance not only covers over the bases of the pyramids, but also sends in prolongations, known as **renal columns**, between the pyramids, towards the sinus. The medullary part of the kidney exhibits in section a striated appearance, while the cortical part is more granular and usually different in colour. The outer, or **basal part**, of each pyramid appears in section to be composed of alternate dark and light streaks, while the inner, or **papillary part**, is often of a lighter colour, and more uniformly and faintly striated.

In sections of the kidney the larger blood-vessels, after they have entered the kidney substance, are seen to lie between the pyramids; and some of their main branches are visible passing across the bases of the pyramids.

In the fœtus and young child, and sometimes, though much less distinctly, in the adult, the surface of the kidney is marked by a number of grooves dividing it into polygonal areas. These represent the **lobes**, or reniculi, of which the kidney is originally composed, and each corresponds to one papilla with its pyramids and surrounding cortical substance.

An examination, with an ordinary pocket lens, of a section through the kidney shows that the lighter striæ of the bases of the pyramids are continued into the cortex. As they pass through the cortex towards the surface of the kidney the striæ become less distinct, and appear, when cut longitudinally, as separate ray-like prolongations carried outward from the bases of the pyramids. These parts of the cortex, which seem, in this way, to be continuations of the medulla, are called "medullary rays" and constitute the **pars radiata** of the cortex. The part

of the cortex which intervenes between them forms what is known as the **pars convoluta** or "labyrinth." The appearance presented by the cortex of the kidney in section varies much according to the plane in which the section has been taken. If the section passes through and lies parallel to the axis of a pyramid, the medullary rays will appear as isolated streaks directed from the base of the pyramid towards the surface of the kidney, and separated from one another by narrow strips, or intervals, of the convoluted part or labyrinth. On the other hand, in sections made at right angles to the axis of a pyramid, or cutting this axis obliquely, the convoluted portion of the cortex presents the appearance of a continuous net, the meshes of which are occupied by the radiate parts, and these latter now exhibit circular or oval outlines. In a similar manner sections through the bases of the pyramids differ much in the appearances they afford according to the plane in which they are cut.

Kidney Tubules.—The glandular substance of the kidney is composed of a vast number of minute **renal tubules**, all of which have an exceedingly complicated course. The wall of each tubule consists throughout of a basement membrane and of an epithelial lining, but the lumen of the tubule and the character of the epithelium vary much in its different parts. Every tubule begins in a thin-walled spherical dilatation, known as **capsula glomeruli** or **Bowman's capsule**, in which a complicated loop of capillary blood-vessels or **glomerulus** is contained. The tuft of capillaries is covered by a reflexion of the delicate wall of the capsule, and is, as it were, invaginated into the capsule (Fig. 964). The capsules with their enclosed capillaries are called **kidney corpuscles**, and are all placed in the convoluted portion of the kidney cortex, where they may be recognised as minute red points just visible to the unaided eye and best marked when the renal vessels are congested. The part of the tubule leading from the capsule —*first convoluted tubule*— is very tortuous, and lies within the convoluted part of the cortex. Passing from the convoluted part, the tubule enters a radiate part, in which its course becomes less complicated, and here it receives the name of *spiral tubule*. From the radiate part the tubule enters the basal portion of the pyramid, and, diminishing in diameter, it pursues a straight course towards the apex of the pyramid, forming the so-called *descending limb of Henle's loop*. Within the apical portion of the pyramid the tubule suddenly bends upon itself, forming the *loop of Henle*, and reversing its direction, it passes back again through the base of the pyramid into the radiate part of the cortex as the *ascending limb of Henle's loop*. This ascending limb exhibits a slight spiral twisting. Leaving the radiate part, the tubule once more enters the convoluted part of the cortex, where its outline becomes so uneven that the name *irregular tubule* is applied to it. While still within the convoluted part, its contour having acquired a more uniform appearance, the tubule receives the name of *second convoluted tubule*; this latter finally ends in a short *junctional tubule*, which passes back into a radiate part of the cortex and joins a *collecting tube*. Each collecting tube receives numerous renal tubules, and pursues a straight course through the radiate part of the cortex and the pyramid. Finally, several collecting tubes, uniting together, form an *excretory tube*, which opens on the summit of a renal papilla into a calyx of the ureter by one of the foramina papillaria already described. In microscopic sections the various portions of the kidney tubule may be distinguished by the position which they occupy and by the character of the lining epithelium.

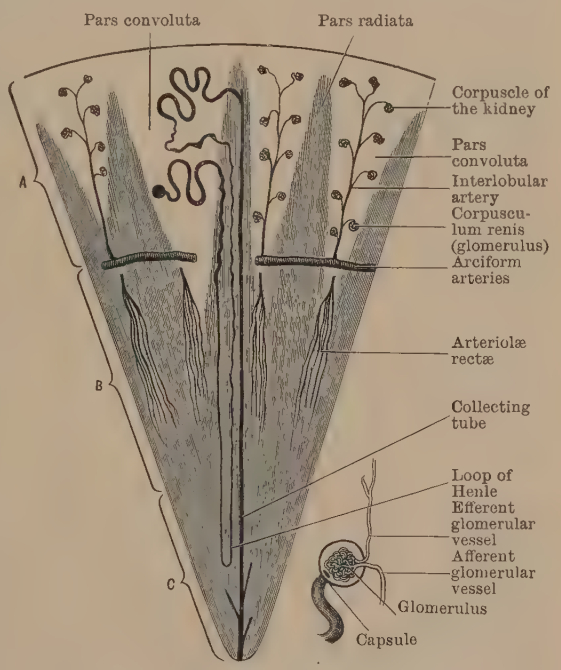

FIG. 964.—DIAGRAMMATIC REPRESENTATION OF THE STRUCTURES FORMING A KIDNEY LOBE.

In the middle part of the figure the course of one of the kidney tubules is indicated, and in the lateral parts the disposition of the larger arteries. A, Cortex; B, Basal portion, and C, Papillary portion of pyramid.

The diagram at the right-hand side of the lower part of the figure illustrates the connexions of the structures composing a renal corpuscle.

Connective Tissue of the Kidney.—The tubules and the blood-vessels forming the substance of the kidney are all united together by a very small amount of connective tissue, which completely surrounds each tubule and blood-vessel, and binds it to its neighbours. It has been found possible to obtain an accurate idea of the arrangement of this connective tissue by submitting thin sections of the kidney to the action of certain digestive fluids. When this is done the tubules and blood-vessels are removed, and the connective-tissue stroma is left behind. The connective tissue thus revealed is seen to form a continuous network, the spaces in which faith-

fully reproduce the outlines and the arrangement of the kidney tubules. The network of the stroma is continuous with the capsule of the kidney.

Vessels of the Kidney.—The renal artery comes directly from the aorta, and is very large in proportion to the size of the organ to which it conveys blood. Its main branches, as they approach the kidney to enter the hilum, lie between the tributaries of the renal vein in front and the ureter behind. Within the sinus of the kidney the branches of the renal artery become arranged in a dorsal and a ventral group, the dorsal vessels lying behind, the ventral ones in front of the subdivisions of the ureter. The ventral group of vessels supplies the part of the kidney which forms the anterior and lateral walls of the sinus; the distribution of the dorsal group is for the most part restricted to the portion of the kidney which lies behind, and to the medial side of the sinus.

Entering the substance of the kidney in the manner described above, the larger arteries lie in the intervals between the pyramids, and are called **interlobar arteries** of the kidney. These vessels dividing, form a series of incomplete arterial arches, the **arteriæ arciformes**, which pass across the bases of the pyramids. Although we speak of arterial arches, it must be understood that no anastomosis between the branches of the interlobar arteries actually takes place, but that each artery which enters the wall of the kidney sinus has an isolated distribution and possesses the characters of an "end artery." Each arterial arch gives off a number of vessels which pass through the convoluted part of the cortex towards the surface of the kidney. These are known as the **interlobular arteries**, and lie at very regular intervals. From them a number of short branches arise, termed **vasa afferentia**, each of which proceeds to the dilated extremity, or capsule, of a kidney tubule. Here the vas afferens breaks up into a much convoluted capillary mass, called a *glomerulus*, which is contained within the invagination of the capsule. The little vein which issues from the glomerulus or **vas efferens**, instead of running directly into a larger vein, breaks up, after the manner of an artery, into capillaries which supply the tubules of the convoluted and radiate parts of the kidney cortex. Hence almost all the blood which supplies the tubules of the cortical part of the kidney passes in the first instance through the glomeruli. The tubules of the bases of the pyramids also receive their blood-supply through vasa efferentia derived from the glomeruli which lie near. The little vessels passing from these latter glomeruli break up into bundles of fine arteries, which give the bases of the pyramids their coarsely striated appearance. They are known as **arteriolæ rectæ**, and, like the interlobular arteries are very conspicuous in injected preparations of the kidney.

The fibrous capsule of the kidney receives minute branches from the interlobular arteries, some of which, piercing the capsule, communicate by capillaries with the vessels of the tunica adiposa.

Veins corresponding to the interlobular arteries and arteriolæ rectæ collect the blood from the capillaries surrounding the tubules, and unite to form a series of complete arches across the bases of the pyramids. From these venous arcades vessels arise, which traverse the intervals between the pyramids and reach the sinus of the kidney, where they unite to form the dorsal and ventral tributaries of the renal vein. Some small veins in the superficial part of the cortex communicate through the fibrous capsule with minute veins in the capsula adiposa. Issuing from the kidney sinus, the renal veins run a direct course to end in the inferior vena cava.

Nerves of the Kidney.—The nerves of the kidney accompany the branches of the artery, and are derived from the renal plexus. Their minute branches form regular net-like plexuses on the walls of the fine arteries and kidney tubules, and the presence of nerve terminations occurring among the epithelial cells lining the tubules has been demonstrated.

From clinical evidence it would appear that the afferent nerve fibres which supply the kidney are connected with the tenth, eleventh, and twelfth thoracic nerves.

The **Lymphatics** of the kidney end in the aortic lymph glands.

Variations.—A marked difference in the size of the two kidneys is sometimes observed, a small kidney on one side of the body being usually compensated for by a large kidney on the opposite side. Cases of complete absence of one or other kidney are recorded.

A few cases are on record in which an extra kidney was found on the right or left side.

Traces of the superficial lobulation of the kidney, present in the fœtus and young child, are often retained in the adult.

Horse-shoe kidney is not an infrequent abnormality. In these cases the two kidneys are united at their inferior ends, across the median plane, by a connecting piece of kidney substance. The amount of fusion between the two kidneys varies much; it is sometimes very complete, while in other cases it is but slight, the connexion being chiefly composed of fibrous tissue.

In very rare cases the kidney appears to be almost entirely surrounded by peritoneum and to be attached to the abdominal wall by a kind of mesentery, enclosing the vessels and nerves passing to the hilum. The condition is believed to be congenital.

Not very infrequently one or both kidneys are found at a much lower level than usual, and occupying a position in the iliac fossa or the pelvic cavity. This condition, when congenital, is associated with an arrest in the normal change in position, relative to surrounding structures, which the kidney experiences during development. In such cases the kidney does not receive its blood-supply from usually placed renal arteries, but from vessels which arise from the lower end of the aorta, or from the iliac, or the middle sacral artery. These congenital abnormally situated kidneys do not usually possess the typical outline of the normal organ, but vary much in shape, and the hilum is often malformed and misplaced.

In some mammalian animals, such as the bear, the kidneys are composed of a number of

completely isolated lobes, each of which corresponds to one papilla, its pyramids and surrounding cortex; while in others, such as the horse, the fusion of the lobes is more complete even than in the human kidney, and a single mass represents the united papillæ.

The Duct of the Kidney.

The duct of the kidney is called the **ureter**, and begins above in a thin-walled funnel-shaped expansion called the **renal pelvis**, which is placed partly within and partly outside the sinus of the kidney. Towards the level of the inferior end of the kidney the part of the pelvis which lies outside the sinus diminishes in calibre, and forms a tube-like duct, the **ureter**, which conveys the urine to the bladder.

The Renal Pelvis.—Within the sinus of the kidney the pelvis lies among the larger renal vessels. It is formed by the junction of two, or more rarely three, thin-walled tubes, the **calyces majores**, each of which has a number of branches. These latter, called **calyces minores**, are short, and increase in diameter as they approach the sinus wall, to which they are attached. Their wide, somewhat funnel-like ends enclose the renal papillæ, and receive the urine which enters them through the foramina papillaria. The calyces are usually about eight in number, one calyx sometimes surrounding two or even three papillæ. The portion of the pelvis that lies outside the kidney has in front of it, in addition to the renal vessels, on the *right side*, the descending part of the duodenum, and on the *left side*, a part of the pancreas and sometimes the duodeno-jejunal flexure (Fig. 959).

The Ureter.—The ureter is the vessel which carries the urine from the pelvis of the kidney to the bladder. It is a pale-coloured thick-walled duct with a small lumen. When *in situ* it has a total length of about ten inches, and lies throughout its whole course in the subperitoneal tissue, behind the peritoneum, to which it is closely connected. In its superior part the ureter lies in the abdominal cavity, and in its inferior part in the pelvis minor (Figs. 961 and 966).

The normal ureter, in the flaccid condition, measures after its removal from the body eleven to fourteen inches.

The **abdominal portion** of the ureter, about five or five and a half inches in length, is directed downwards and slightly medially, and lies upon the psoas major muscle (Fig. 958). Certain structures are related to the ureters in a similar manner on both sides of the body; for instance, the abdominal portion of each ureter is crossed very obliquely, on its anterior aspect, by the internal testicular vessels, and behind each ureter the genito-femoral nerve passes downwards and laterally. Other structures are related to the duct of the right or left side alone. On the *right side*, the descending part of the duodenum lies in front of the upper part of the ureter, and the line of attachment of the mesentery crosses it lower down, just before the ureter enters the cavity of the pelvis minor. The right colic and ileo-colic arteries may also be anterior relations. On the *left side* the left colic artery and the line of attachment of the mesentery of the pelvic colon cross the ureter.

Crossing the common iliac, or the external iliac artery, the ureter enters the pelvis minor. The left ureter usually crosses the common iliac artery, and the right ureter, in most cases, lies across the external iliac; but this arrangement is by no means constant.

In X-ray photographs, the shadow cast by the abdominal portion of the ureter when the latter has been rendered opaque, is seen to fall immediately in front of the tips of the transverse processes of the lower lumbar vertebræ.

The **pelvic portion** of the ureter is about four and a half or five inches in length; it passes downwards on the side wall of the pelvis, immediately behind the peritoneum, describing a curve which is convex backwards and laterally (Fig. 966). The most convex portion of this curve lies close to the deepest part of the greater sciatic notch (Fig. 966). As it descends upon the side wall of the pelvis the ureter forms the posterior boundary of the triangular district known as the obturator triangle. The lower limit of this triangle is formed by the ductus deferens, and

the upper and anterior boundary by the external iliac vessels and the pelvic brim (Fig. 966).

In its course within the pelvis minor the ureter lies in front of the hypogastric artery, and crosses the medial aspect of the obturator nerve and vessels and of the obliterated umbilical artery. About the level of the ischial spine, the ureter is crossed from before backwards by the ductus deferens, and from this point onwards it is not so intimately related to the peritoneum. It now bends somewhat medially and forwards, to reach the lateral angle of the bladder, and comes into relationship with the upper end of the vesicula seminalis, in front of which it lies (Fig. 940). The ductus deferens having crossed the ureter also turns medially, and as it does so it lies on a posterior plane to the ureter. The inferior end of the ureter is surrounded by a dense plexus of veins which brings the vesical plexus into communication with the hypogastric vein. The great nerve cord which connects the hypogastric plexus with the pelvic plexus, also comes into relationship with the lower part of the pelvic portion of the ureter, in the region where the latter is crossed by the ductus deferens (Fig. 940).

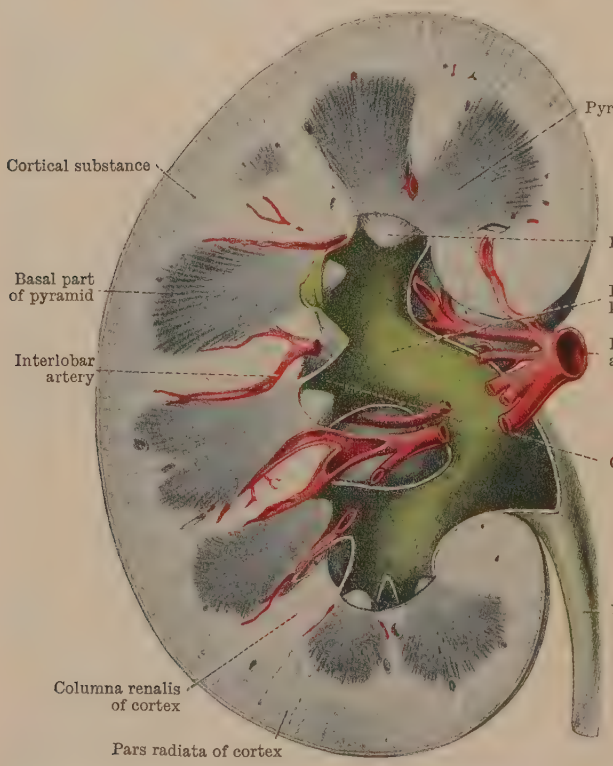

FIG. 965.—LONGITUDINAL SECTION OF THE KIDNEY, OPENING UP THE KIDNEY SINUS.

The pelvis of the kidney and some of its calyces have been laid open as they lie within the sinus.

When the right and left ureters reach the bladder they are a little more than two inches apart. They pierce the bladder wall very obliquely, and are embedded within its muscular tissue for nearly three-quarters of an inch of their length. Finally, they open into the bladder by two small slit-like apertures which are of a valvular nature, and prevent a backward passage of fluid from the bladder. It is probable, however, that an exaggerated idea of the valvular nature of the openings of the ureters into the bladder is obtained by an examination of the parts in the dead subject. When the bladder is empty the openings of the ureters are placed about one inch apart, but when that viscus is distended they are often two inches, or more, distant from one another. As the ureter pierces the bladder wall the muscular fibres of the bladder and ureter remain quite distinct, and so the ureter, remaining a thick-walled tubular structure, appears to pass through a gap in the muscular wall of the bladder. The mucous coat alone of the ureter becomes continuous with that of the bladder.

The lumen of the ureter is not uniform throughout, but is somewhat constricted in certain places, corresponding to the regions where the ureter is most sharply curved or changes its direction. These more constricted parts of the tube are described as occurring one in the middle of the abdominal portion, one at the junction of the abdominal and pelvic portions, and one in the pelvic part of the ureter. Also just before the ureter joins the pelvis of the kidney and just as it reaches the bladder wall its lumen is usually somewhat constricted.

In the female, the ureter, near its termination, passes beneath the lower part of the broad ligament of the uterus, and lies to the lateral side of the cervix uteri and the upper part of the lateral wall of the vagina. It is accompanied in the inferior part of its course by the uterine artery, which crosses it on its anterior aspect not far from its termination. Higher up it lies in the peritoneal ridge which forms the posterior boundary of the fossa ovarica, which, in the female, is a posterior subdivision of the obturator triangle (Fig. 966).

Structure of the Ureter.

The wall of the ureter, which is thick and of a whitish colour, is composed of mucous, muscular, and fibrous coats. The **tunica mucosa**, or mucous coat, possesses an epithelium composed of many layers of cells, those nearest the surface being of large size. When the canal

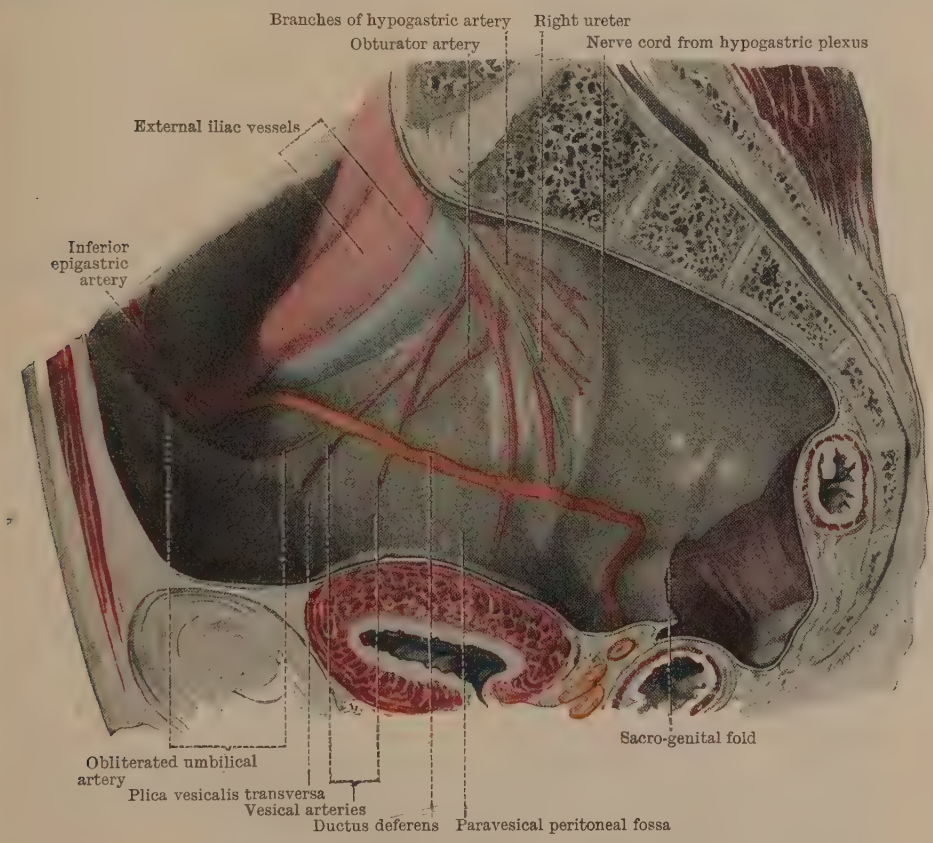

Fig. 966.—Median Section of an Adult Male Pelvis.

The coils of the small intestine and of the colon which lay within the pelvis have been lifted out in order to give a view of the side wall of the pelvic cavity.

is empty the mucous coat is thrown into numerous longitudinal folds, and so its lumen exhibits a stellate outline in transverse section. The submucous tissue varies much in thickness in different parts of the ureter, and contains some elastic fibres. The unstriated muscle fibres which compose the **tunica muscularis**, or muscular coat, are collected into bundles which are separated by a considerable amount of connective tissue, and are arranged, some longitudinally, some circularly. In the upper part of the ureter a relatively large amount of connective tissue is present deep to and among the bundles of muscle fibres, which are arranged in three distinct strata—an inner longitudinal, an intermediate circular, and an outer longitudinal. In the middle part of the vessel the same layers may be recognised, but the circularly disposed bundles of fibres are more numerous than higher up. In the lower part of the ureter the connective tissue is relatively scanty and the inner longitudinal fibres lie close to the lining epithelium; in this region also the longitudinal folds of the mucous coat become fewer and less marked. A short distance above the point where it reaches the bladder, a number of coarse bundles of longitudinally arranged muscle fibres are applied to the outer surface of the muscular coat of the ureter. These form the so-called "sheath of the ureter." In the portion of the ureter which traverses the wall of the bladder nearly all the fibres of the muscular coat are disposed longitudinally.

The muscle fibres lie close beneath the epithelium, and end just where the mucous coats of the bladder and ureter become continuous. The **tunica adventitia**, or outer fibrous coat, of the ureter varies in thickness at different levels, and in its lower part blends with the connective tissue which lies among the muscle fibres forming the sheath of the ureter just mentioned.

The mucous membrane of the calyces and of the pelvis of the kidney possesses an epithelium resembling that of the ureter. Where each renal papilla projects into one of the calyces a deep circular recess, or fornix, is formed between the wall of the calyx and the sloping side of the papilla; at the bottom of this recess the epithelium of the calyx becomes continuous with that covering the papilla. At the foramina papillaria the epithelium joins that of the kidney tubules. The muscular fibres in the wall of the calyces and of the pelvis are collected into loosely arranged bundles separated by wide intervals occupied by fibrous connective tissue. As in the ureter, the outermost and innermost fibres run in a longitudinal, the intermediate ones in a circular direction. The circularly arranged fibres alone form a distinct layer.

Vessels and Nerves of the Ureter.—The abdominal part of the ureter receives its blood-supply from the renal and internal spermatic arteries; the pelvic portion is supplied by the vesical and middle hæmorrhoidal vessels.

The nerves of the ureter are derived from the renal, spermatic, and hypogastric plexuses. The afferent fibres reach the spinal cord through the eleventh and twelfth thoracic, and first lumbar nerves.

Variations.—The ureter is sometimes represented by two tubes in its upper portion. In rarer cases it is double throughout the greater part of its extent, or even in its whole length from the pelvis of the kidney to the bladder. In such cases there may be two openings into the bladder. Asymmetry as regards such abnormalities is very common.

Variations in the form of the pelvis of the kidney are of frequent occurrence. Most usually the pelvis divides into two large subdivisions, one of which passes in the direction of the upper, the other in that of the lower pole of the kidney. In some cases these branches come off directly from the ureter without the intervention of a pelvis, or a marked subdivision may lead to the formation of two pelves.

VESICA URINARIA.

The **urinary bladder** is a hollow muscular organ situated in the anterior part of the pelvic cavity, above and behind the symphysis pubis. It lies in front of the rectum, from which it is separated *in the male* by the seminal vesicles and the terminal portions of the deferent ducts, and *in the female* by the vagina and uterus. The ureters, which convey the fluid secreted by the kidneys, open into the lower part of the bladder about half an inch from the median plane.

The urethra, or canal by which the urine reaches the surface, leads from the bladder, its vesical aperture lying in the median plane, below and anterior to the openings of the ureters. The size and shape of the bladder, the thickness of its wall, and also to a great extent its relations, vary with the amount of distension, or contraction, of the organ. When empty, or only slightly distended, the bladder lies within the pelvis minor; as it becomes filled with urine it rises above the pubis, and crossing the pelvic brim enters the abdominal cavity. These changes affect chiefly the upper part of the bladder, which becomes altered in shape and size, and acquires new connexions and relations; the lower portion varies but slightly with the amount of distension of the organ (see Figs. 967 and 968). The upper part of the bladder is covered with peritoneum, which is reflected on to it from the anterior abdominal wall in front, from the sides of the pelvis laterally, and, *in the male*, across the seminal vesicles and terminal parts of the deferent ducts from the rectum behind. *In the female* the peritoneum passes on to the bladder posteriorly from the anterior surface of the uterus. The peritoneum dips down posteriorly for a certain distance between the bladder and rectum in the male, forming the recto-vesical or recto-genital pouch; in the female a slit-like peritoneal recess, called the utero-vesical pouch, intervenes between the anterior surface of the uterus and the bladder (Fig. 973).

The inferior part of the bladder lies below the peritoneum, and is for the most part directed towards the pelvic floor. Anteriorly in the median plane it is supported by the symphysis pubis and the retro-pubic pad of fat in both sexes. Farther back, *in the male*, it rests upon the prostate and on the lower part of the rectum, from the latter of which it is separated by the vesiculæ seminales and the terminal portions of the deferent ducts. *In the female* it rests upon the anterior wall of the vagina.

Laterally, on each side, the bladder is supported by the levator ani muscle

and farther from the median plane by the obturator internus; it is separated from the layer of fascia covering these muscles by loose areolar tissue.

The opening of the urethra, or **internal urethral orifice**, is placed in, or near, the part of the bladder wall which lies lowest in the pelvic cavity. The term neck, or cervix, is often applied to this region, the bladder appearing as if it were suddenly constricted to form the urethra.

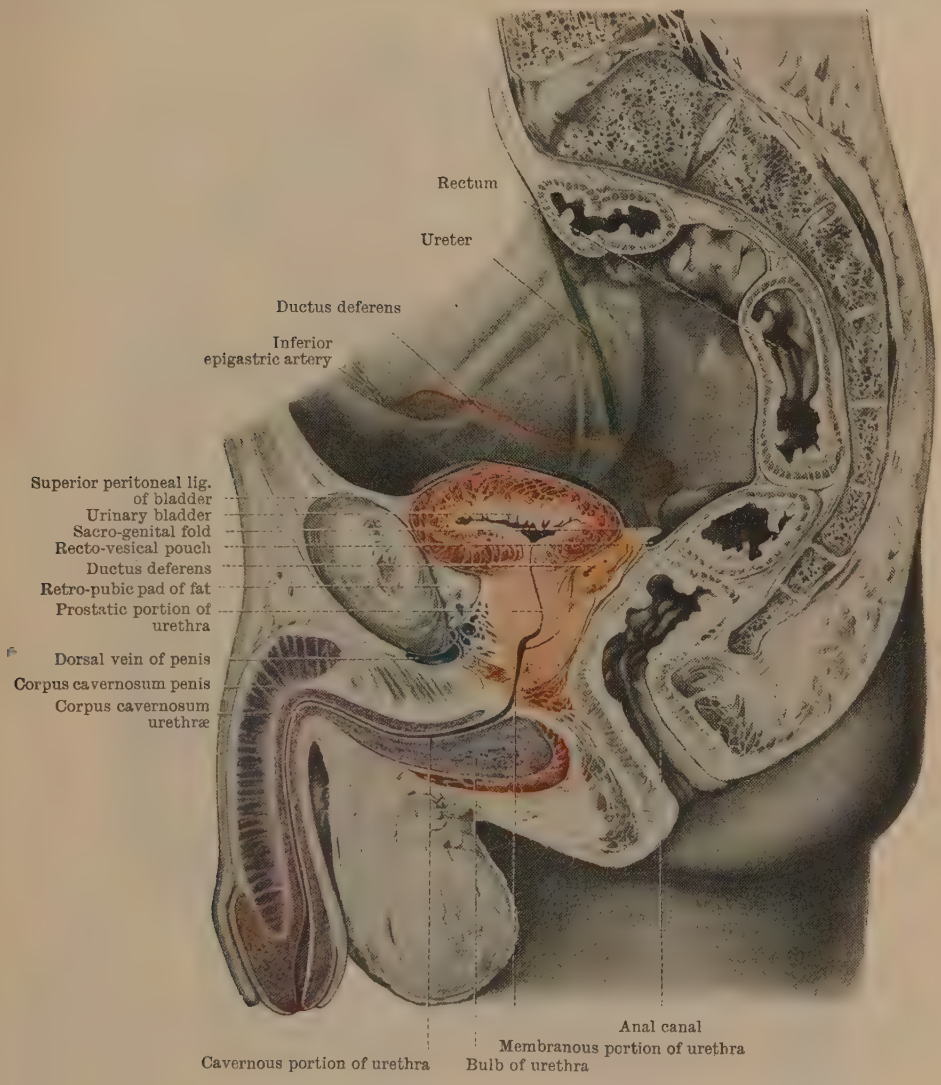

FIG. 967.—MEDIAN SECTION THROUGH THE PELVIS OF AN ADULT MALE SUBJECT.

The urinary bladder is empty and firmly contracted. The coils of small intestine have been removed to afford a view of the side wall of the pelvic cavity.

The portion of the bladder wall posterior to the urethral orifice, which is directed *in the male* towards the anterior wall of the rectum and lies below and in front of the recto-vesical pouch, is called the **fundus vesicæ**; it is closely related to the seminal vesicles and ampullæ of the deferent ducts. The corresponding part of the bladder *in the female* rests against the anterior wall of the vagina.

The term **vertex vesicæ** is applied to the portion of the bladder which lies nearest to the upper border of the symphysis pubis when the organ is empty, and rises high above the pubis into the abdominal cavity when the bladder is distended. Connected with the vertex of the bladder is a fibrous cord, the median umbilical ligament, or **urachus**, which passes upwards, in the median plane, on the

posterior aspect of the anterior abdominal wall, and reaches the umbilicus. It represents the passage which in the embryo connects the developing bladder with the allantois.

The part of the bladder connecting the vertex with the base, and not sharply marked off from either, is called the **corpus vesicæ**, or body of the bladder.

Position of the Urethral Orifice.—During the various changes in shape and size which the bladder undergoes, the region of the internal urethral orifice remains

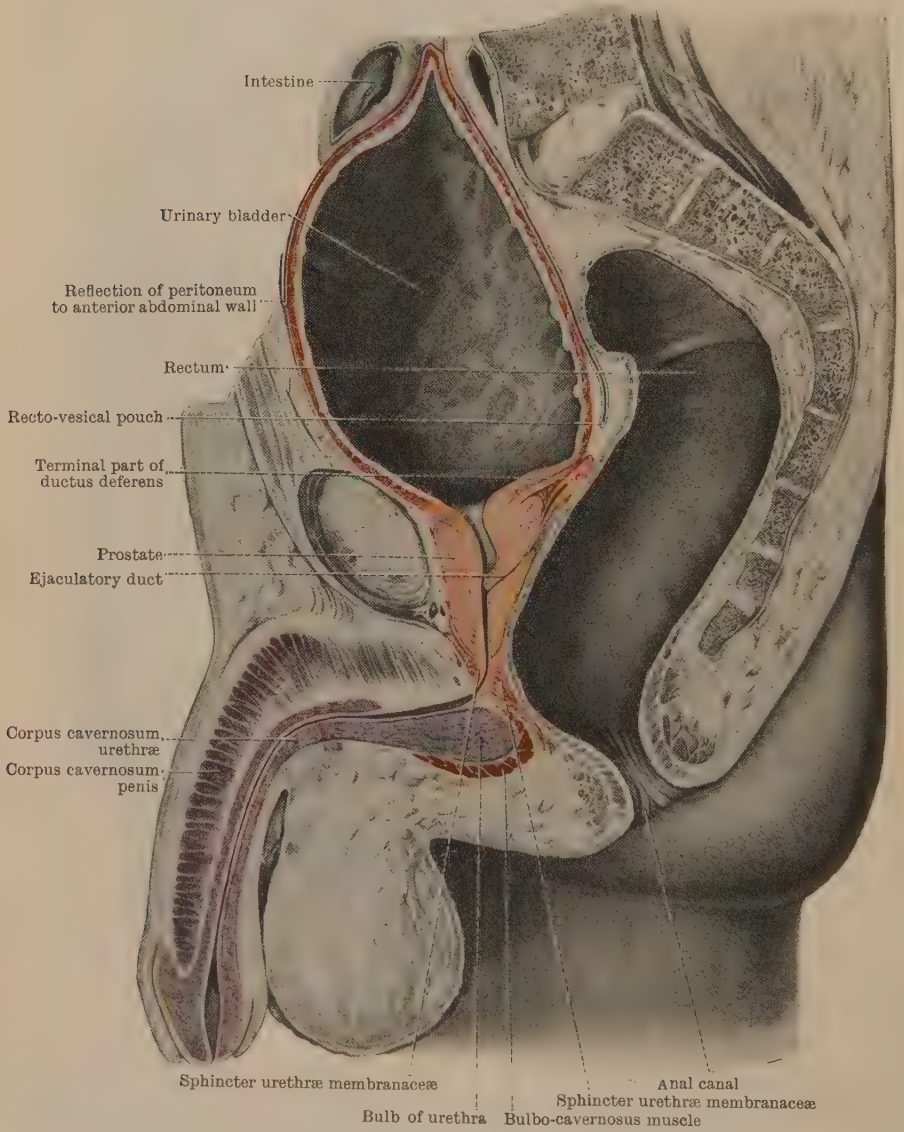

FIG. 968.—MEDIAN SECTION OF THE PELVIS OF AN ADULT MALE SUBJECT.
The urinary bladder and rectum are both distended.

almost fixed in position. In the male the urethral orifice lies immediately above the prostate, and behind and slightly below the level of the upper margin of the symphysis pubis, from which it is distant about two to two and a half inches. It can be reached by a finger introduced into the bladder through the abdominal wall above the symphysis pubis. It is usually placed half an inch to one inch above the level of a plane passing through the lower margin of the symphysis and the lower end of the sacrum, but in some cases it is found to be somewhat lower. The comparatively slight variations in the level of the internal urethral orifice which

do occur, depend partly upon the quantity of fluid contained in the bladder, and partly upon the amount of distension of the lower portion of the rectum. When the bladder is very much distended this region lies at a slightly lower level in the pelvis than when the organ is empty. On the other hand, distension of the lower part of the rectum raises, to some extent, the level of the urethral orifice. Since the position of the internal urethral orifice varies, in the manner just described—with the condition of the rectum and of the bladder—it follows that it lies at its lowest limit when the bladder is full and the rectum empty, and at its highest level when the bladder is empty and the rectum distended. In the female the internal urethral orifice normally occupies a lower level than in the male (compare Figs. 968 and 973).

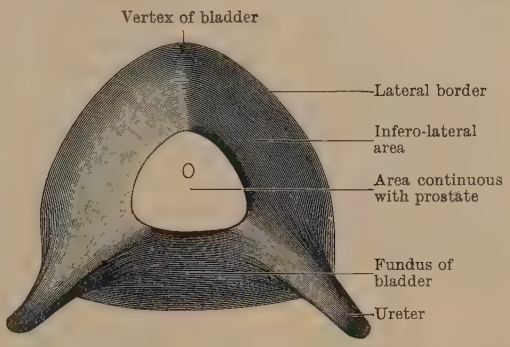

FIG. 969.—INFERIOR ASPECT OF THE EMPTY MALE URINARY BLADDER. From a subject in which the viscera had been hardened *in situ*.

The prostate has been severed from the bladder, and the white area in the drawing indicates the position where the two structures were continuous.

Inferior Aspect of the Bladder.—The lower part of the bladder, which is directed towards the pelvic floor, changes, as we have seen, but slightly with the varying amount of distension of the viscus. When the organ has been hardened before its removal from the body, it is possible to map out on its inferior aspect three convex triangular areas, which may be distinguished from one another by the directions in which they look. The three areas approach one another in the region of the urethral orifice, where, in the male, a portion of the inferior aspect of the bladder wall is structurally continuous with the upper part of the prostate. Posterior to the urethral orifice is a triangular district, directed downwards and backwards, and related, *in the male*, to the seminal vesicles and the terminal portions of the deferent ducts, which, together with the recto-vesical fascia, intervene in this position between the bladder and the rectum. This triangular area corresponds to the **fundus** of the bladder, and *in the female* it is directed against the anterior wall of the vagina. The rest of the inferior aspect of the bladder is formed by two **infero-lateral areas**, or surfaces, which meet in the median plane in front of the urethral orifice, and are directed for the most part downwards and laterally (see Fig. 971). Each of these areas extends backwards to join the fundus along a rounded border which lies between the point where the ureter reaches the bladder and the urethral orifice. The infero-lateral area of the bladder wall rests on the areolar tissue covering the fascia of the levator ani and the obturator internus muscles, and, nearer the median plane, upon the os pubis and the retro-pubic pad of fat.

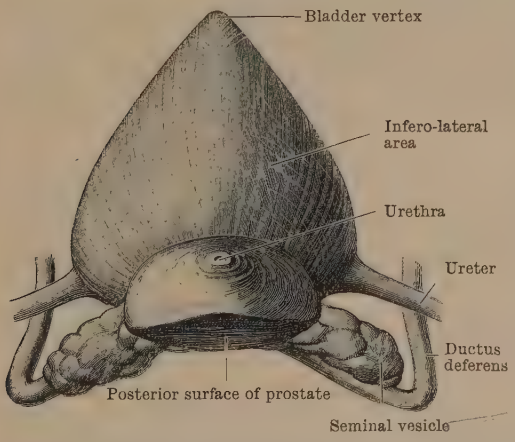

FIG. 970.—THE URINARY BLADDER, PROSTATE, AND SEMINAL VESICLES, VIEWED FROM BELOW.

Taken from a subject in which the viscera were hardened *in situ*. Same specimen as Fig. 971, A. The bladder contained but a small amount of fluid.

The three rounded borders which mark off the three triangular areas on the inferior aspect of the bladder, just described, extend from the region of the urethral orifice to the vertex of the bladder, and to the points where the ureters reach the bladder wall (Figs. 969, 970).

Shape and Relations of the Empty Bladder.—When the bladder is empty, or

nearly so, it has, roughly speaking, the shape of an inverted tetrahedron, the apex of which corresponds to the point where the urethra leaves the organ, while the base of the tetrahedron is formed by the superior surface of the bladder. The three basal angles of the tetrahedron correspond to the bladder vertex and to the two **lateral angles** of the bladder, or points where the ureters join the organ. The three surfaces, which meet inferiorly at the urethral orifice, are only marked off from one another by rounded borders, but as long as the organ is empty, or nearly so, they are separated by distinct borders from the superior surface. These three areas have been already described as the infero-lateral surfaces and the fundus of the bladder (Fig. 969). Their relations have also been indicated. The **superior surface** of the empty bladder looks upwards into the pelvic cavity; it is convex when the organ is contracted, concave when relaxed. This surface is covered by peritoneum, and its outline, which is approximately triangular, is determined by lateral and posterior borders. The **lateral borders** of the empty bladder are sharply marked, and extend from the bladder vertex to the lateral angles of the bladder, or points where the ureters join the organ. They separate the superior surface from the infero-lateral portions of the inferior aspect of the bladder

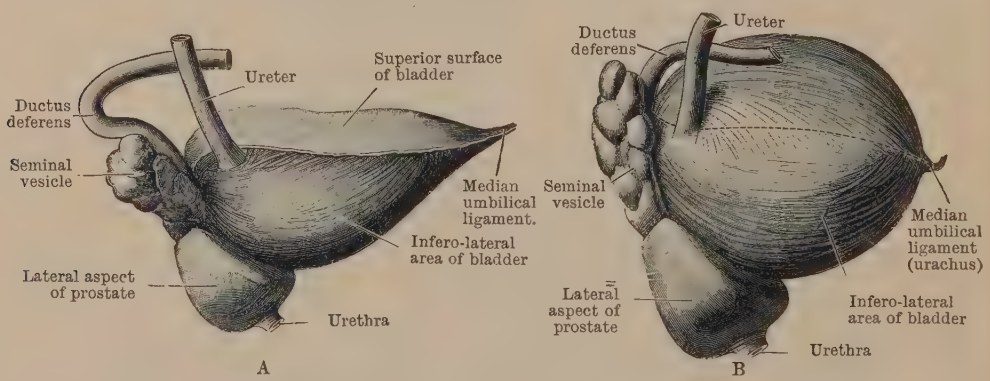

FIG. 971.—THE URINARY BLADDER, PROSTATE, AND VESICULA SEMINALIS, VIEWED FROM THE LATERAL ASPECT.

Drawn from specimens in which the viscera were hardened before removal from the body. In A the bladder contained but a very small quantity of fluid; in B the quantity was somewhat greater. In A the peritoneum is shown covering the superior surface of the bladder, and its cut edge is seen where it is reflected along the lateral border of the organ. In B the level of the peritoneal reflexion is indicated by a dotted line.

wall (Fig. 971, A). The **posterior border** stretches across between the lateral angles of the bladder, and separates the superior surface from the fundus. The superior surface is related *in the male* to coils of intestine; *in the female* it is related also to the anterior surface of the uterus. The lateral border of the empty bladder lies against the lining fascia of the pelvis just above, or at the level of, the arcus tendineus. The ductus deferens crosses the side wall of the pelvis parallel to it, but at a considerably higher level (Fig. 967).

In median section the cavity of the empty and relaxed bladder often presents the appearance of a Y-shaped chink, the stem of the Y being represented by the urethra as it leaves the organ, and the two limbs by the narrow intervals between the superior surface and the under parts of the bladder wall which lie in front of and behind the urethral orifice. This relaxed form is sometimes described as the diastolic condition of the empty bladder, and is found associated with a bladder wall of but little thickness, and with a concave upper surface. The condition is usually the result of an escape of fluid after death, when the bladder wall has lost the power of contracting. It does not represent a normal condition of the organ in the living. The normal empty bladder is strongly contracted, and its wall is thick and firm. A distinctly Y-shaped appearance is not presented by its cavity in median section, but the interior of the organ is seen as a simple narrow interval continuous with the canal of the urethra.

Distended Bladder.—As the bladder fills with fluid the superior wall is raised upwards from the fundus and infero-lateral walls. At the same time, the borders separating the superior from the other surfaces of the bladder become at first more rounded and then nearly obliterated (Fig. 971). The lateral borders of

the bladder becoming in this manner opened out, give rise to so-called **lateral surfaces** in the distended organ. These surfaces, however, are not sharply marked off, and are directly continuous with the superior surface. During distension, the angles present in the empty condition of the organ become rounded as the entire bladder wall becomes more uniformly convex. The general shape of the bladder becomes altered; the tetrahedral form of the empty organ is lost, and the bladder as it becomes filled assumes first a somewhat spherical, then an oval contour. The enlarging bladder comes to occupy more and more of the pelvic cavity, displacing upwards the portions of the colon and small intestine which may lie in the pelvis when the organ is empty. Until all the available pelvic space has been filled, the form of the distended bladder is spherical, or oval with the larger end directed downwards and backwards. When the pelvic wall prevents further expansion of this portion,

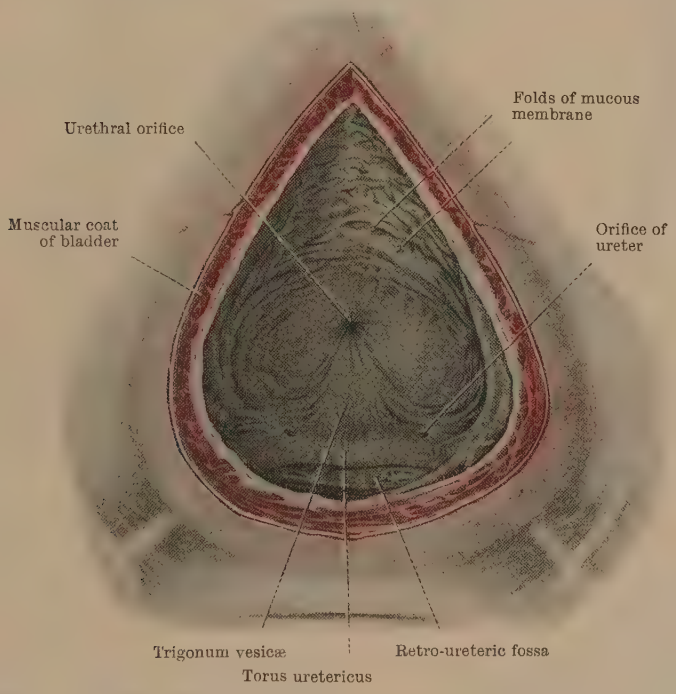

FIG. 972.—EMPTY AND CONTRACTED URINARY BLADDER, OPENED UP BY THE REMOVAL OF ITS UPPER WALL.
The peritoneum is seen spreading out from the lateral and posterior borders of the organ. Compare with Fig. 967.

the outline of the organ may become an oval, with the larger end directed upwards and forwards into the abdominal cavity. The highest part of the distended bladder does not correspond to the attachment of the urachus at the apex, but to a point farther back. As the superior wall of the bladder is raised up during distension it carries with it the peritoneum, and thus the reflexion of that membrane, from the anterior abdominal wall on to the vertex of the bladder, comes to lie one and a half inches, or even more, above the upper margin of the symphysis pubis (Fig. 973). It is, therefore, possible to puncture, or open into the distended bladder, through the anterior abdominal wall above the symphysis pubis, without at the same time opening into the peritoneal cavity. In a similar manner the line of reflexion of the peritoneum, from the side wall of the pelvis on to the lateral aspect of the bladder, is raised higher during distension, and may come to correspond, in part, to the level of the ductus deferens, or to that of the obliterated umbilical artery. On the other hand, the level of the reflexion of the peritoneum from the rectum towards the basal aspect of the bladder does not vary much with the distension, or contraction, of the organ (compare Figs. 967 and 968), and thus the fossa between the bladder and rectum

becomes relatively very deep when the bladder is full. The bladder in normal distension may contain nearly one pint, but in most cases the organ is emptied when its contents reach from six to ten ounces. Under abnormal or pathological conditions the bladder capacity may be very much increased.

Varying Relationships, according to the degree of Distension of the Bladder.—The lateral aspect of the distended bladder may be related to the obliterated umbilical artery as it passes forwards on the side wall of the pelvis. When the bladder is empty its lateral border lies about one and a quarter inches below this artery. The ductus deferens, during a part of its course, is in contact

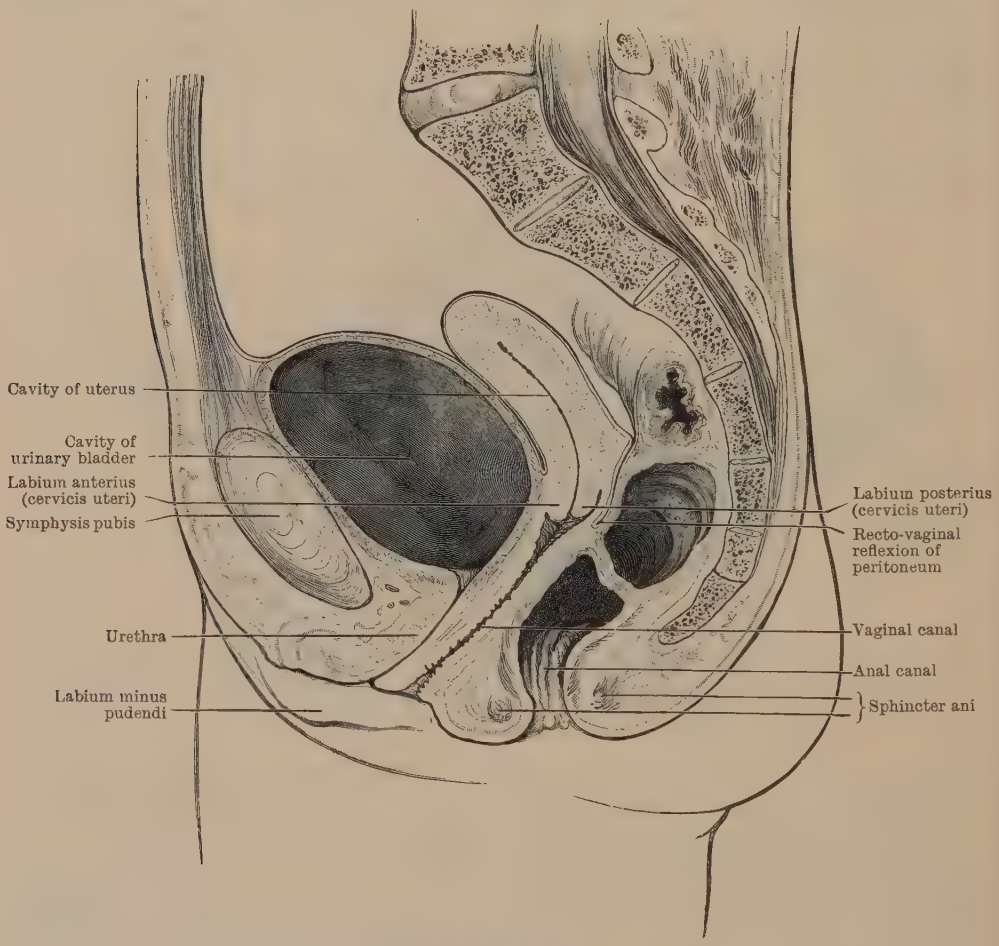

FIG. 973.—MEDIAN SECTION OF THE PELVIS IN AN ADULT FEMALE.
The cavity of the uterus is indicated diagrammatically.

with the lateral wall of the distended bladder, but lies above and parallel to the lateral border when the organ is empty. The side wall of the distended bladder is closely related to the obturator vessels and nerve.

Interior of the Bladder.—The mucous membrane lining the bladder is loosely connected to the muscular coat, and when the bladder is contracted the mucous lining is thrown into a number of prominent wrinkles or folds (Fig. 972). At one place only the mucous membrane is firmly connected to the subjacent muscular coat, and the inner surface of this part of the bladder wall is smooth and free from wrinkles. This smooth area corresponds to a triangular surface behind the urethral orifice, called the **trigonum vesicæ**, and to the part of the bladder wall which immediately surrounds the opening. The apex of the triangle lies at the beginning of the urethra, and the base is formed by a

line drawn between the openings of the ureters into the bladder. Just behind the urethral opening the bladder wall sometimes bulges slightly into the cavity, owing to the presence of the middle lobe of the prostate, which lies beneath the mucous coat in this position. When well marked, as it often is in old people, this bulging is termed the **uvula vesicæ**. Stretching across between the openings of the ureters there is usually to be seen a smooth ridge, due to the presence of a bundle of transversely disposed muscle fibres, which lies within this part of the bladder wall, beneath the mucous membrane. This ridge has been called the "**torus uretericus**" (Fig. 972). It may be deficient near the median plane, and it is curved so as to be convex forwards. The lateral portions of the ridge which lie lateral to the openings of the ureters are called the **plicæ uretericæ**, and are produced by the terminal parts of the ureters as they traverse the bladder wall and lie beneath the mucous coat of the bladder. In old people the region behind the trigonum is often depressed and forms a shallow *retro-ureteric fossa*. A less distinct depression may sometimes be observed on each side of the trigonum. Round the urethral orifice are a number of minute radially disposed folds which, disappearing into the urethra, become continuous with the longitudinal folds of the mucous membrane of the first part of that canal. The ureter pierces the bladder wall very obliquely, and so the minute ureteral orifice has an elliptical outline. The lateral boundary of each opening is formed by a thin, crescentic fold, which, when the bladder is artificially distended in the dead subject, acts as a valve in preventing water or air from entering the ureter. Hence the term "valvula ureteris" is sometimes used to designate the fold. In the empty bladder the urethral orifice and the openings of the two ureters lie at the angles of an approximately equilateral triangle, the sides of which are about one inch in length. When the bladder is distended the distance between the openings may be increased to one and a half inches or more.

Bladder in the Female.—In the female the bladder is related posteriorly to the uterus and upper part of the vagina. The anterior surface of the uterus in its upper part is separated from the upper surface of the bladder by the shallow utero-vesical pouch of peritoneum, but the two organs are nevertheless normally in apposition. So close is this relationship that the upper surface of the bladder very often shows a slight concavity, due to contact with the convex anterior wall of the uterus. The lower part of the uterus and upper part of the vagina are not separated by peritoneum from the fundus of the bladder, but are united to it by areolar connective tissue (Fig. 973). Thus, below the level of the utero-vesical pouch, the female bladder is related in much the same manner to the uterus and anterior wall of the vagina as the male bladder is related to the seminal vesicles and deferent ducts. The vertex of the bladder, where the urachus is attached, often lies on a lower level than in the male, so that the organ, even when distended, rises less freely into the abdomen. The bladder as a whole is placed deeper in the pelvis than in the male, and the internal urethral orifice lies just above, or just below, a line drawn from the lower margin of the symphysis to the lower end of the sacrum (p. 1260). The lower level of the internal urethral orifice is probably correlated with the absence of a distinct prostate in the female. It is probable that as regards capacity no difference exists between the bladder in the male and in the female; the conflicting results arrived at by different observers are probably due to the faulty methods which have been employed in estimating the capacity of the organ.

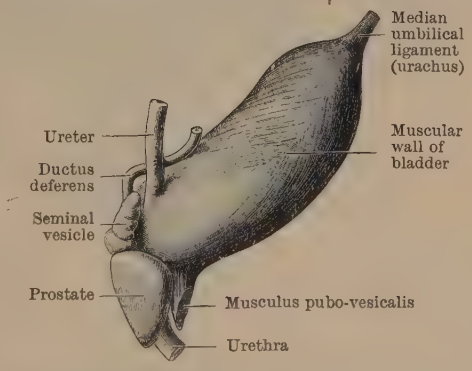

FIG. 974.—THE URINARY BLADDER OF A NEWLY-BORN MALE CHILD, viewed from the side. The drawing is from a specimen which had been hardened *in situ*.

Bladder in the Newly-born Infant and in the Child.—At birth the empty

bladder is spindle- or torpedo-shaped, and its long axis, which extends from the point of attachment of the urachus to the internal urethral orifice, is directed downwards and backwards (Fig. 974). The lateral and posterior borders seen in the adult organ cannot be recognised at birth, nor is there any part of the bladder wall directed downwards and backwards, as is the fundus of the adult organ. In the fœtus and young child the bladder occupies relatively a much higher level than it does in the adult, and, even when empty, it extends upwards into the abdominal cavity. Its anterior aspect is in contact with the posterior surface of the anterior abdominal wall. At birth the peritoneum forming the recto-vesical pouch covers the whole of the posterior aspect of the bladder, and reaches as low as the upper limit of the prostate. The internal urethral orifice is placed at a high level, and sinks gradually after birth (Fig. 975). In the newly-born child this opening lies on a level with the upper margin of the symphysis pubis, and the openings of the ureters lie almost on a level with the plane of the pelvic brim. The obliterated umbilical arteries are more intimately related to the bladder in the child than in the adult, and lie close against its sides as they pass upwards on the posterior aspect of the anterior abdominal wall towards the umbilicus (Fig. 988).

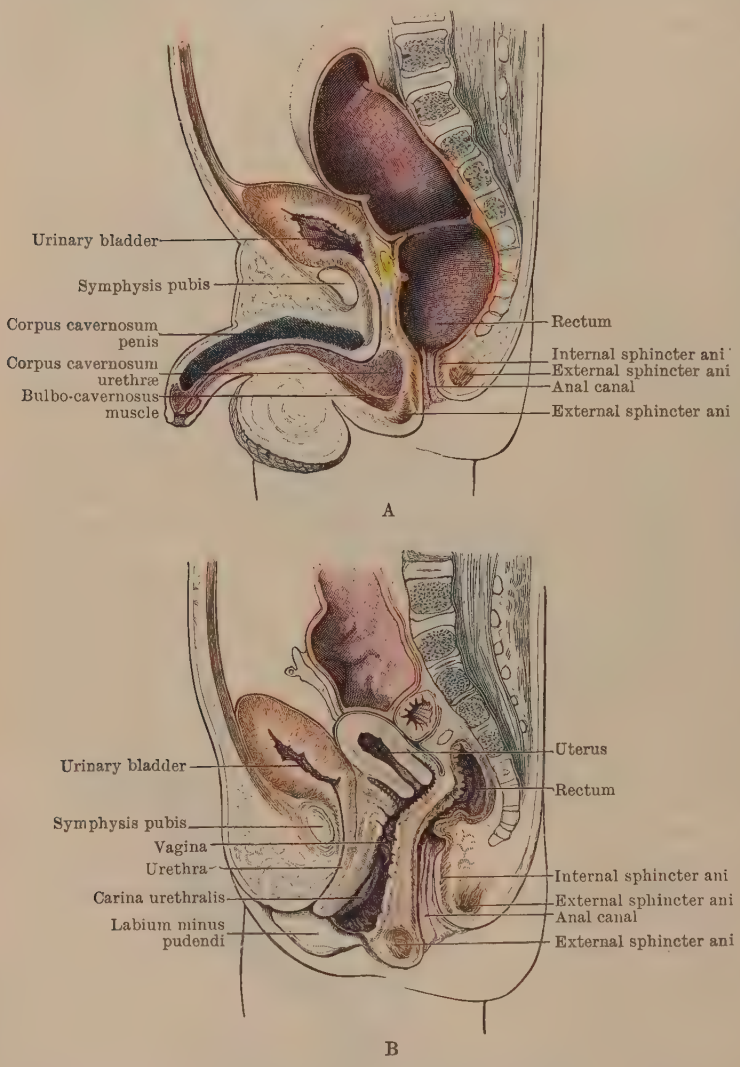

FIG. 975.—MEDIAN SECTION THROUGH THE PELVIS OF NEWLY-BORN CHILD.
A, Male, and B, Female.

Peritoneal Relations and Connexions of the Bladder.—We have already seen that the superior surface of the empty bladder is covered by peritoneum, which leaves it along the lateral border on each side to reach the pelvic wall about the level of the arcus tendineus of the levator ani muscle. To this peritoneal reflexion the term **lateral peritoneal ligament** is often applied. The lateral peritoneal ligaments of opposite sides are continuous in front, at the bladder vertex, where the peritoneum is conducted over the fibrous cord of the urachus to reach the anterior abdominal wall, forming the so-called **superior peritoneal ligament**. When the bladder is empty the level of this anterior reflexion lies just

behind, or just below, the upper margin of the symphysis pubis. When the bladder becomes filled the level of the peritoneal reflexion forming the superior peritoneal ligament is raised upwards, and may reach a point one and a half inches, or more, above the upper margin of the symphysis pubis. Similarly, the line along which the lateral peritoneal ligament reaches the pelvic wall is also carried upwards in distension of the bladder, and may reach the level of the ductus deferens and of the obliterated umbilical artery.

When the bladder is empty the peritoneum is carried downwards upon the side wall of the pelvis as low as the lateral border of the organ, and lines a shallow

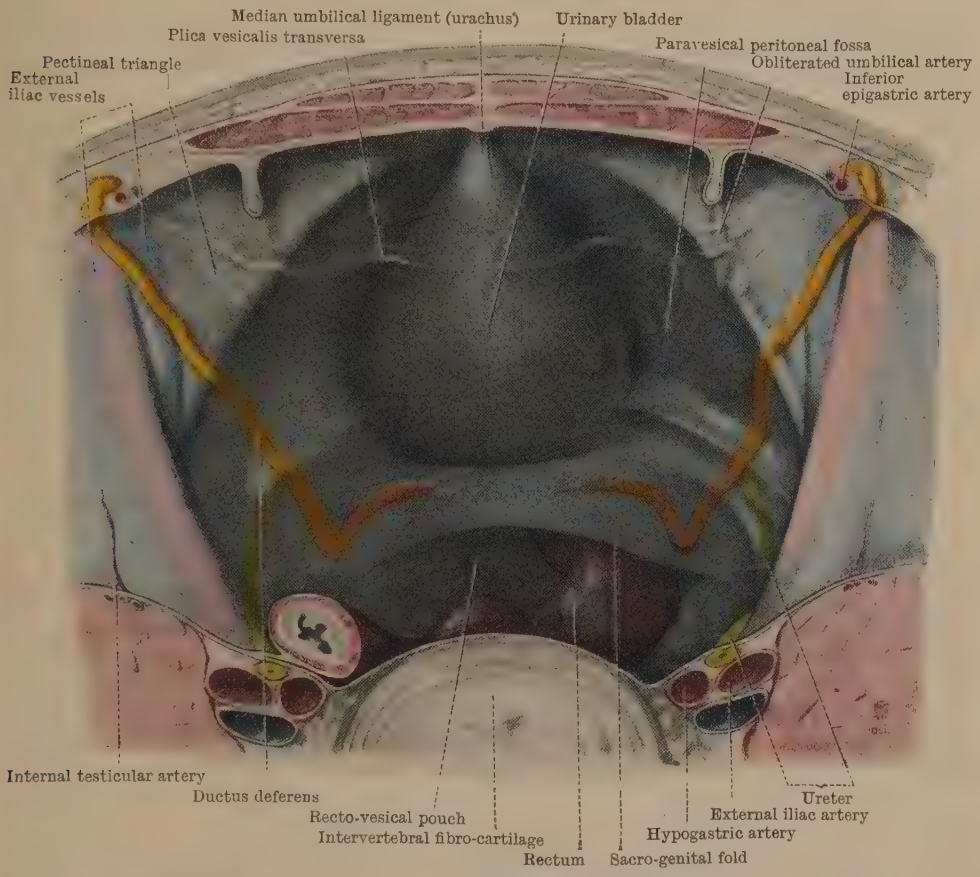

FIG. 976.—VIEW LOOKING INTO THE MALE PELVIS FROM ABOVE AND SOMEWHAT BEHIND.

From a specimen in which the bladder was firmly contracted and contained but a small amount of fluid. The paravesical fossa is seen on each side of the bladder. The peritoneal pouch in front of the rectum is bounded on each side by the crescentic sacro-genital folds or "posterior peritoneal ligaments of the bladder," which meet together in the median plane some distance behind the posterior border of the bladder.

depression which receives the name of **paravesical fossa** (Figs. 976, 941). This peritoneal fossa lies below the level of the obturator triangle (p. 1255), from which it is separated by the ductus deferens. As the bladder fills, the peritoneum is raised off this part of the pelvic wall, and certain structures, such as the obturator vessels and nerve and the ductus deferens, which lie on the lateral wall of the pelvis, come into direct relationship with the lateral aspect of the distended bladder.

Posteriorly the peritoneum leaves the superior surface of the empty bladder at its posterior border, and is carried backwards, forming a kind of horizontal shelf, or fold, for a distance of about half an inch, giving at the same time a partial covering to the deferent ducts and superior ends of the seminal vesicles. The peritoneum then suddenly dips downwards to reach the bottom of the recto-vesical, or recto-genital, pouch, where it is reflected on to the anterior surface of the rectum

(Figs. 944, 967). As a rule, no part of the fundus of the contracted and empty bladder receives a covering from the peritoneum, since the seminal vesicles and terminal portions of the deferent ducts intervene as they lie in the anterior wall of the recto-vesical or recto-genital pouch. When the bladder is distended the posterior border, separating the upper surface and fundus, is rounded out, and the peritoneum forming the horizontal shelf, just described, is taken up (compare Fig. 968). It is to be specially noted that the level of the peritoneal reflexion, forming the bottom of the recto-vesical pouch, does not vary much, as regards its relationship to the prostate, during distension and contraction of the bladder (Figs. 967 and 968).

An examination of median sections of the pelvis shows the great danger run by the ampullæ of the deferent ducts in any operation for reaching the bladder through the anterior wall of the rectum, and the difficulty in avoiding injury to the peritoneum.

The term "**posterior peritoneal ligament**" is sometimes applied to the somewhat variable crescentic fold of peritoneum which bounds, on each side, the entrance to the recto-vesical or recto-genital pouch, and which often unites with the fold of the opposite side across the median plane, behind the posterior border of the bladder and the ductus deferentes (Figs. 966 and 976). These folds represent the recto-uterine folds found in the female, and are to be regarded as connexions of the deferent ducts rather than of the bladder; hence the name **sacro-genital folds** is applicable to these structures in both sexes.

The peritoneum covering the upper surface of the empty or partly distended bladder often exhibits a transversely disposed fold or wrinkle, known as the **plica vesicalis transversa**. This fold, when well developed, can be traced on to the side wall of the pelvis, where it traverses the paravesical fossa, and in some cases it is found to cross the pelvic brim and to be directed towards the abdominal inguinal ring (Fig. 976).

In the female the peritoneum is reflected posteriorly from the upper surface of the bladder on to the anterior aspect of the uterus and forms the **utero-vesical peritoneal ligament.**

Fixation of the Bladder.—When the **medial umbilical ligament**, or fibrous cord of the urachus, which binds the bladder vertex to the anterior abdominal wall, and the peritoneal connexions, already described, are severed, the bladder is easily moved about, except in its lower part. Except in the region of the fundus and of the internal urethral orifice the bladder wall is connected to the pubis and lining fascia of the pelvis by loose areolar tissue and thus free movement is permitted during expansion and contraction of the organ.

The lower fixed part of the bladder is held in place chiefly by its firm connexion with the prostate, with which indeed it is structurally continuous. The prostate is surrounded by a dense fibrous sheath from which strong fascial connexions pass anteriorly to the back of the pubis and on each side to the lining fascia of the pelvis. These fibrous connexions are known as the pubo-prostatic and lateral ligaments of the prostate, and by fixing the prostate they maintain the lower part of the bladder in position.

In the female similar fibrous connexions exist for the upper part of the urethra, and in both sexes the region of the internal urethral orifice is the most fixed part of the bladder wall.

The pubo-prostatic ligaments contain bundles of smooth muscle fibres continuous with those forming the muscular coat of the bladder, and these are known as the **pubo-vesical muscle.**

Behind the urethral orifice the region of the fundus receives fixation and support from the dense fibrous tissue and strands of unstriped muscle which surround the seminal vesicles and the terminal portions of the ureters and deferent ducts. On each side many of the fibrous and muscular strands forming this support are continued into the fascia surrounding the branches of the hypogastric artery.

In the female the fundus of the bladder wall is supported and held in place by its connexion with the anterior wall of the vagina.

Structure of the Bladder Wall.—The wall of the bladder from without inwards is composed of a serous, a muscular, a submucous, and a mucous coat. The **serous coat** formed by peritoneum is incomplete, and covers only the upper and posterior parts of the distended bladder (Fig. 968).

A considerable amount of loose connective tissue surrounds the **muscular coat**, and penetrating it, divides it into numerous coarse bundles of muscle fibres. All the muscle fibres are of the unstriped variety, and the bundles which they form are arranged in three very imperfectly separated strata called external, middle, and internal. The **external stratum** is for the most part made up of fibres which are directed longitudinally, and it is best marked near the median plane on the upper and under aspects of the bladder. Farther from the median plane, on the sides of the bladder, the fibres composing the external stratum run more obliquely, and their directions frequently cross one another. In the male, many of the fibres of the external stratum pass both anteriorly and posteriorly into the prostate, and in the female the corresponding fibres join the dense tissue which in this sex forms the upper part of the wall of the urethra. Other fibres of this stratum on each side of the middle line join the lower part of the symphysis pubis and constitute the **musculus pubovesicalis**, which follows the course of the pubo-prostatic ligament. Lastly, some fibres of the external stratum blend posteriorly with the anterior aspect of the rectum and receive the name of **musculus rectovesicalis**. The **middle stratum** is composed of fibres which for the most part run circularly, and form the greater part of the thickness of the muscular coat. In the region of, and behind, the urethral orifice the bundles of fibres are finer and more densely arranged, and surround the opening in a plane which is directed obliquely downwards and forwards. This part of the middle stratum is often spoken of as the "sphincter vesicæ." Inferiorly the fibres of the sphincter vesicæ are continuous with the muscular tissue of the prostate in the male, and with the muscular wall of the urethra in the female. In other parts of the bladder the bundles of the middle stratum are coarser and separated by intervals filled by connective tissue. The **internal stratum** is composed of a thin layer of muscle fibres directed for the most part longitudinally.

The **submucous coat** is composed of areolar tissue, but contains numerous fine elastic fibres.

The **mucous coat** is loosely attached, by means of the submucous layer, to the subjacent muscular coat, except in the region of the trigonum vesicæ. Here the muscular fibres lie close beneath, and are firmly adherent to the mucous membrane. Over the trigonum the mucous coat is always smooth and flat; elsewhere it is thrown into folds when the bladder is empty. The mucous membrane of the bladder is continuous with that of the ureters and urethra. The epithelium, covering it, varies much in appearance in different conditions of the organ, and is of the variety known as transitional stratified epithelium. The appearance of the mucous coat is described on p. 1264.

When as a result of urethral obstruction the muscular coat of the bladder becomes hypertrophied, strong strands of muscular tissue become raised up and project into the cavity of the bladder. The resulting net-like arrangement of ridges resembles the trabeculæ carneæ of the heart ventricle.

Vessels and Nerves of the Bladder.—The bladder receives its blood supply on each side from the **superior** and **inferior vesical** branches of the hypogastric artery. The largest **veins** are found just above the prostate, and in the region where the ureter reaches the bladder. They form a dense plexus which pours its blood into tributaries of the hypogastric vein, and communicates below with the pudendal venous plexus.

The **lymph-vessels** from the bladder join the iliac group of lymph-glands.

The **nerve** supply of the bladder is derived on each side from the **vesical plexus**, the fibres of which come from two sources, namely (1) from the **upper lumbar nerves** through the hypogastric plexus, and (2) from the **third** and **fourth sacral nerves**. The fibres from the latter sources join the vesical plexus directly.

THE URETHRA.

The **urethra** is the channel which serves to convey the urine from the bladder to the exterior. In the *male* it consists of two portions, a proximal part, less than one inch in length, extending from the bladder to the points where the ducts of the reproductive glands join the canal, and a much longer distal portion which serves as a common passage for the secretion of the kidneys and for the generative products. An account of the male urethra follows the description of the male reproductive glands and passages (see p. 1289). In the *female* the urethra is more simple in its arrangement, and represents only the proximal part of the male canal. It is a short passage leading from the bladder to the external urethral orifice—an aperture placed within the pudendal or uro-genital cleft, immediately above and in front of the opening of the vagina.

Urethra Muliebris.—The **female urethra** is a canal of about one to one and a half inches in length which follows a slightly curved direction downwards and forwards, below and behind the lower border of the symphysis pubis. As it leaves the pelvis the urethra pierces the uro-genital diaphragm. The part of the passage which lies between the superior and inferior layers of the uro-genital diaphragm is surrounded by the fibres of the sphincter urethræ membranaceæ muscle. Except during the passage of fluid the canal is closed by the apposition

of its anterior and posterior walls. The **external urethral orifice** is placed between the labia minora, immediately in front of the opening of the vagina, and lies about one inch below and behind the clitoris (Fig. 1007). The opening is slit-like, and is bounded by slightly marked lateral lips. The posterior wall of the urethra, except in its upper part, is very intimately connected with the anterior wall of the vagina. As it approaches the external urethral orifice the urethra is practically embedded in the anterior vaginal wall. The mucous lining of the canal is raised into a number of slightly marked longitudinal folds, one of which, more distinct than the others, and placed upon the posterior wall of the passage, receives the name of **crista urethralis**.

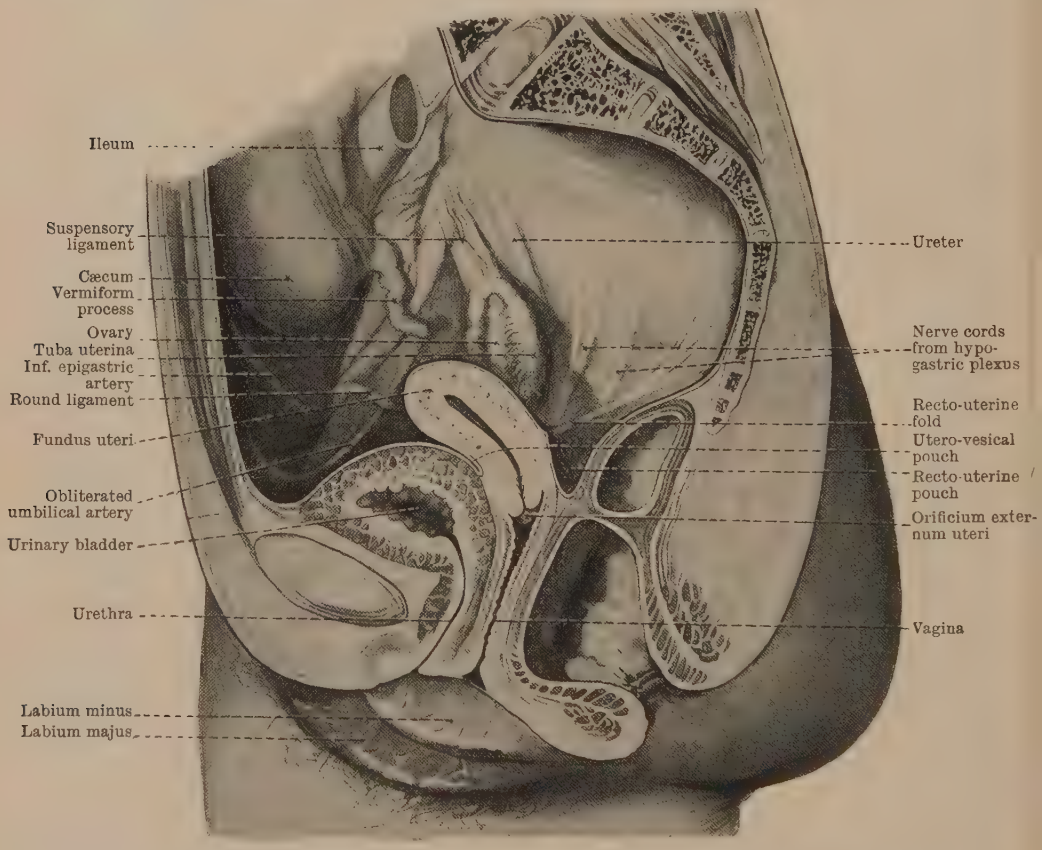

Fig. 977.—Median Section through the Female Pelvis. Drawn for the most part from a model of a dissection by Professor Edward H. Taylor.

Structure.—The wall of the female urethra is thick and contains much fibrous tissue which passes without any sharp line of demarcation into the surrounding mass of connective tissue. The thick **muscular coat** of the urethra is continuous above with that of the bladder, and is composed of layers of circularly disposed smooth muscle fibres, together with a few bundles which are longitudinally directed. Within the muscular coat the wall of the urethra is very vascular, and the canal itself is lined by a pale mucous membrane which is thrown into longitudinally directed folds, one of which is the crista urethralis mentioned above. The epithelium of the canal, in its upper part, is of the transitional variety, like that of the bladder; in its lower part it becomes scaly. Numerous minute **urethral glands** and pit-like **urethral lacunæ** open into the urethra. One group of these glands on each side possesses a minute common duct known as the **para-urethral duct**, which opens into the uro-genital cleft by the side of the external urethral orifice. These latter glands represent the prostatic glands of the male subject. The vascular layer which lies between the muscular coat and the mucous membrane contains elastic fibres, and in appearance resembles erectile tissue. Striped muscle fibres are present on the outer aspect of the muscular coat of the urethra. In the upper part of the canal these fibres form a complete ring-like sphincter, but in the middle and lower parts the striped muscle fibres, though present in front, are absent on the posterior wall of the urethra, as at this level they pass backwards on the outer aspect of the vagina, and enclose this latter passage together with the urethra in a single loop of muscle tissue. The lower fibres, therefore, form a uro-genital sphincter.

THE MALE REPRODUCTIVE ORGANS.

We have here to describe (1) the testes or essential reproductive glands of the male, together with their (2) coverings and (3) ducts, (4) the prostate, (5) the bulbo-urethral glands, (6) the external genital organs, and (7) the male urethra.

The reproductive glands of the male, or **testes**, are a pair of nearly symmetrical oval-shaped bodies situated in the scrotum. The duct of each gland, at first much twisted and intertwined, forms a structure known as the **epididymis**, which is applied against the posterior and lateral part of the testis. From the epididymis the excretory duct, or **ductus deferens**, passes upwards towards the inferior part of the anterior abdominal wall, which it pierces very obliquely, to enter the abdominal cavity. Here each ductus deferens is covered by the peritoneum, and, crossing the pelvic brim, almost at once enters the pelvis minor. The duct now runs on the side wall of the pelvis towards the base of the bladder, where it comes into relation with a branched tubular structure termed the **vesicula seminalis**. Joined by the duct of the vesicula seminalis, the ductus deferens forms a short canal called the **ejaculatory duct**, which terminates by opening into the prostatic part of the **urethra**. The **prostate**, a partly glandular, partly muscular structure, surrounding the first part of the urethra, and also the **bulbo-urethral glands**, are accessory organs connected with the male reproductive system. The ducts of the bulbo-urethral glands and those of the prostate, like the ejaculatory ducts, open into the urethra, which thus serves not only as a passage for urine, but also for the generative products. The external genitals are the **penis** and **scrotum**.

THE TESTIS.

The male reproductive glands, the **testes**, are a pair of somewhat oval, slightly flattened bodies of a whitish colour, measuring about an inch and a half in length, one inch from before backwards, and rather less in thickness. Each testis is placed within the cavity of the scrotum in such a manner that its long axis is directed upwards, slightly forwards, and laterally. Usually the left gland occupies a lower level than the right. The testis (Fig. 979) has two somewhat flattened surfaces; a *lateral surface* which looks backwards as well as laterally, and a *medial surface*, which looks forwards as well as medially, and is usually the more flattened. The two surfaces are separated by two rounded borders, one of which, the *anterior border*, is the more convex and free; while the other, the *posterior border*, is less rounded. By the posterior border the testis is suspended within the scrotum. The **epididymis** and the lowest portion of the **funiculus spermaticus**, or *spermatic cord*, are attached to the posterior border of the testis. Each border

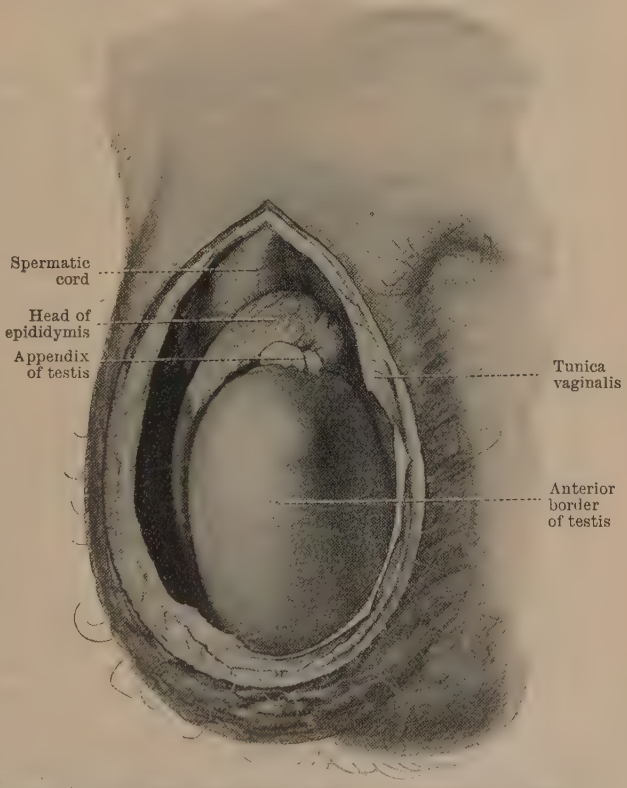

Fig. 978.—Right Testis and Epididymis, exposed by the Removal of the Anterior Wall of the Scrotum.

ends above in the *superior extremity*, and below in the *inferior extremity* of the testis. Owing to an obliquity of the long axis of the gland, the superior extremity of the testis lies on a more anterior and lateral plane than the inferior extremity.

Epididymis.—The epididymis is a somewhat crescentic structure, which is curved round the posterior border of the testis and overlaps to some extent the posterior part of the lateral surface of that organ. The superior, somewhat swollen part is called the **head of the epididymis**, and overhangs the superior end of the testis, to which it is directly connected by numerous emerging ducts, by connective tissue, and by the serous covering of the organ. The inferior and smaller end is termed the **tail of the epididymis**, and is attached by loose areolar tissue and by the serous covering to the inferior end of the testis. The intermediate part, or **body of the epididymis**, is applied against, but is separated from, the posterior part of the lateral surface of the testis by an involution of the serous covering of the organ, which forms an intervening pocket termed the **sinus of the epididymis.**

The main mass of the epididymis is composed of an irregularly twisted canal, the **duct of the epididymis**, which forms the first part of the duct of the testis.

Minute sessile, or pedunculated, bodies are often found attached to the head of the epididymis or to the superior end of the testis. These are called appendices of the epididymis and testis, and have a developmental interest. The minute body which lies on the superior end of the testis represents the free end of Müller's duct in the embryo and the fimbriated end of the uterine tube of the female; it is usually sessile. Above the head of the epididymis, and in front of the lower part of the spermatic cord, there may also be present a small vestigial body called the **paradidymis**. This is rarely seen in the adult, and is best marked in young children.

Tunica Vaginalis.—The cavity within which the testis and epididymis are placed is lined by a smooth serous membrane—the **tunica vaginalis**—which resembles in appearance and structure the peritoneum, from which it is originally derived. The cavity is considerably larger than the contained structures, and extends not only down to a lower level than the testis, but also reaches upwards to a higher level than the gland. The sac, or cavity, tapers as it is traced upwards, and above the level of the testis the spermatic cord bulges forwards into its posterior part. The tunica vaginalis is reflected from the posterior wall of the scrotal chamber over the testis and epididymis, giving a covering to each. The part of the membrane lining the cavity is called the **parietal lamina** of the tunica vaginalis, while the part clothing the testis and epididymis is termed the **visceral lamina**. Between the lateral surface of the testis and the body of the epididymis, the visceral lamina of the tunica vaginalis dips in and lines a narrow interval called the **sinus of the epididymis**. The entrance to the sinus is limited above and below by short crescentic folds of the tunica vaginalis, which pass from the testis to the head and tail of the epididymis. These folds are spoken of as the *superior* and *inferior ligaments* of the epididymis. In three positions the surface of the testis receives no covering from the tunica vaginalis—superiorly where the head is attached, inferiorly where the cauda epididymidis is in contact, and posteriorly where the blood-vessels and nerves enter the organ from the funiculus spermaticus or spermatic cord.

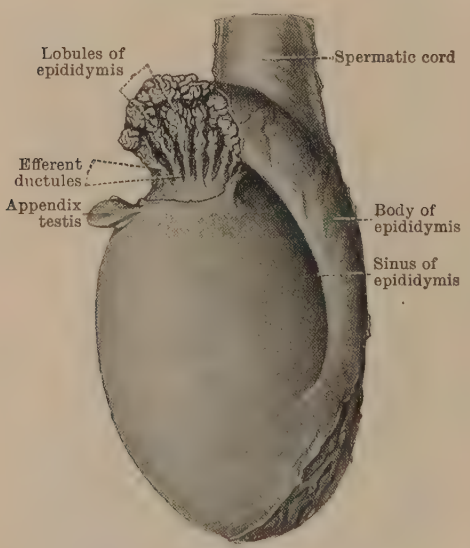

FIG. 979.—LEFT TESTIS AND EPIDIDYMIS.

A part of the tunica vaginalis has been removed in order to show the ductuli efferentes and lobuli epididymidis.

Structure of the Testis.—Beneath the serous tunica vaginalis the testis is invested by an external coat, composed of dense white inelastic fibrous tissue called the **tunica albuginea**, from the deep surface of which a number of slender fibrous bands, or septa, dip into the gland. These—the **septula testis**—imperfectly divide the organ into a number of wedge-shaped parts called **lobuli testis** (Fig. 980). All the septa end posteriorly in a mass of fibrous tissue which is directly continuous with the tunica albuginea, and which projects forwards into the testis along its posterior border. This structure receives the name of **mediastinum testis**, and is traversed by an exceedingly complicated network of fine canals, into which the minute tubules which compose the substance proper of the testis open. The mediastinum is also pierced by the arteries, veins, and lymph vessels of the testis. These vessels enter the posterior border of the organ, and traversing the mediastinum, spread out on the fibrous septa which radiate towards all parts of the deep surface of the tunica albuginea. In this way a delicate network of vessels (tunica vasculosa) is formed on the deep surface of the tunica albuginea and on the sides of the septula.

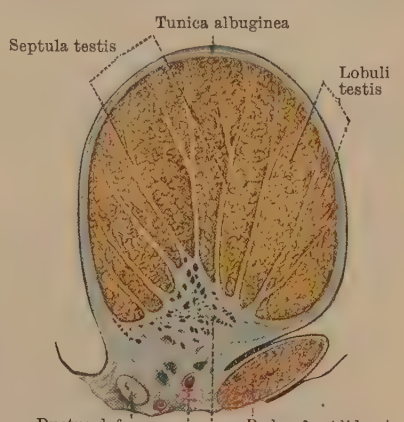

FIG. 980.—TRANSVERSE SECTION OF THE TESTIS AND EPIDIDYMIS.

The mediastinum, the septula, and the tunica albuginea form a framework enclosing a number of imperfectly isolated spaces which are filled by a loosely packed substance of a light brown colour called the **parenchyma testis.**

The parenchyma is composed of enormous numbers of much-convoluted seminiferous tubules, called **tubuli seminiferi contorti**, and completely fills up the intervals between the septula. The minute tubules look like fine threads to the unaided eye, and are but loosely held together by a small amount of connective tissue. Usually two or four tubules are found in each lobule of the gland, and the total number in the testis has been estimated at about 600. The seminiferous tubules pass towards the mediastinum testis and unite at acute angles, to form a smaller number of slender tubes which run a straight course. These latter are called **tubuli seminiferi recti**, and open into a complicated network of fine canals situated in the substance of the mediastinum, called the **rete testis.** The tubules are much more twisted and convoluted in the cortical part of the gland, near the tunica vaginalis, than in the region of the mediastinum. According to some observers, they give off side branches which may effect anastomoses between the tubules. Recent observations lead to the conclusion that each convoluted tubule is to be regarded as an arched canal opening by both its ends into a straight tubule.

Microscopic sections show that the walls of the seminiferous tubules are composed of a basement membrane and of an epithelial lining, formed of several layers of cells. Certain cells of this epithelium are, in the adult, constantly undergoing transformation into **spermatozoa**, and the appearance of the tubules in section varies much, according to age and to the greater or less activity of the epithelial cells.

Structure of the Epididymis.—The secretion of the contorted seminiferous tubules is carried through the tubuli seminiferi recti into the rete testis, and leaves the latter, to reach the canal of the epididymis, through from fifteen to twenty minute tubules called **ductuli efferentes testis.** These efferent ductules pierce the tunica albuginea and enter the head of the epididymidis where it is in direct contact with the superior extremity of the testis. Each ductule is at first straight, but soon becomes much convoluted, and forms a little conical mass of twisted tubule, called a **lobule of the epididymis,** or conus vasculosus. Within the head of the epididymis the little twisted canals finally open into the single much-convoluted tube which constitutes the chief bulk of the epididymis, and is called

the **duct of the epididymis**. This canal, which is not less than 19 or 20 feet in length, may be said to begin in the head of the epididymis, and to end, after an extraordinarily tortuous course, at the tail by becoming the **ductus deferens** (Fig. 981).

In most cases one or more slender convoluted diverticula from the duct of the epididymis may be found near its lower end. These receive the name of **ductuli aberrantes**, and one of them which is very constantly present often measures a foot or more in length.

The duct of the epididymis and the efferent ductules are lined by a ciliated epithelium, the cilia of which maintain a constant current towards the ductus deferens. The duct possesses a muscular coat composed of an inner stratum of circularly and an outer stratum of longitudinally directed fibres. The wall, at first thin, becomes much thicker as the duct approaches the ductus deferens.

Vessels and Nerves of the Testis.—The testis is supplied by the **testicular artery**, a branch of the aorta. This slender vessel, after a long course, reaches the posterior border of the testis, where it breaks up into branches which enter the mediastinum testis, and are distributed along the septula and on the deep surface of the tunica albuginea.

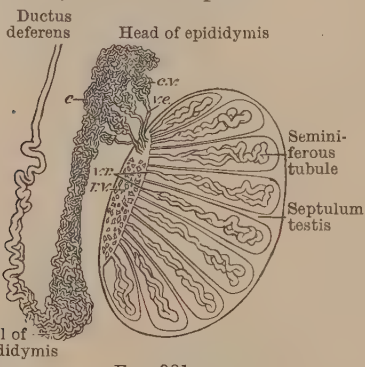

FIG. 981.

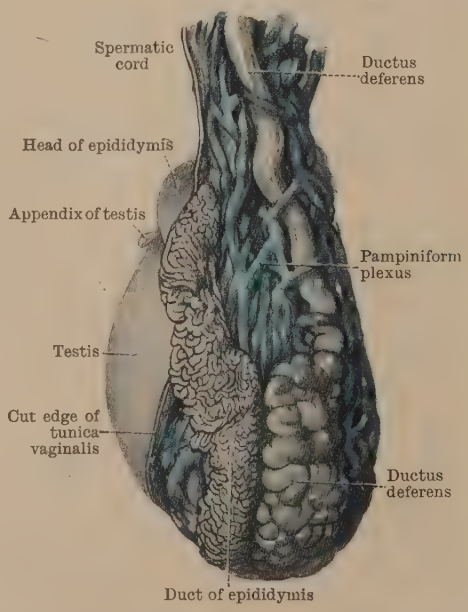

FIG. 982. — LEFT TESTIS AND EPIDIDYMIS VIEWED FROM BEHIND, showing the ductus epididymidis and the first part of the ductus deferens.

The **veins** issuing from the posterior border of the testis form a dense plexus, called the **pampiniform plexus**, which finally pours its blood through the testicular vein, *on the right side*, into the inferior vena cava, and *on the left side*, into the left renal vein.

The **nerves** for the testis accompany the artery, and are derived through the **aortic** and **renal plexuses** from the tenth thoracic segment of the spinal cord. The afferent fibres from the epididymis appear to reach the spinal cord through the posterior roots of the eleventh and twelfth thoracic and first lumbar nerves. The arteries and nerves of the testis communicate with those on the lower part of the ductus deferens, namely, with the artery of the ductus deferens and with twigs from the hypogastric plexus.

The **lymph-vessels** of the testis pass upwards in the spermatic cord, and end in the lumbar lymph-glands.

DUCTUS DEFERENS.

The **ductus deferens** is the direct continuation of the duct of the epididymis. Beginning at the inferior extremity of the epididymis, it ends, after a course of nearly 18 inches, by opening as the **ejaculatory duct** into the prostatic, or first, part of the urethra. The duct in parts of its course is somewhat convoluted, and the actual distance traversed by it is not more than 12 inches. Placed in the first instance outside the abdominal cavity, the deferent duct ascends within the scrotum towards the lower part of the anterior abdominal wall, which it reaches not far from the median plane. During this part of its course the duct, together with the vessels and nerves of the testis, is surrounded by a number of loose coverings derived from certain layers of the abdominal wall, and the cord-like structure so formed is termed the **funiculus spermaticus** or spermatic cord. The

deferent duct, together with the accompanying vessels and nerves, now passes through the abdominal wall in an oblique passage, to which the name **inguinal canal** is applied. Within the abdomen the duct lies immediately beneath the peritoneum, and soon crossing over the pelvic brim, it enters the pelvis minor, on the side wall of which it proceeds backwards towards the fundus of the bladder. Here, near the median plane, the deferent duct is joined by the duct of the corresponding **seminal vesicle** and the ejaculatory duct, thus formed, having traversed the prostate, opens into the urethra.

At first the ductus deferens, like the canal from which it takes its origin, is very tortuous, but soon increasing in thickness, it becomes less twisted, and passes upwards along the medial side of the epididymis, behind the testis, to enter the spermatic cord (Fig. 980). Its course is now almost vertically upwards towards

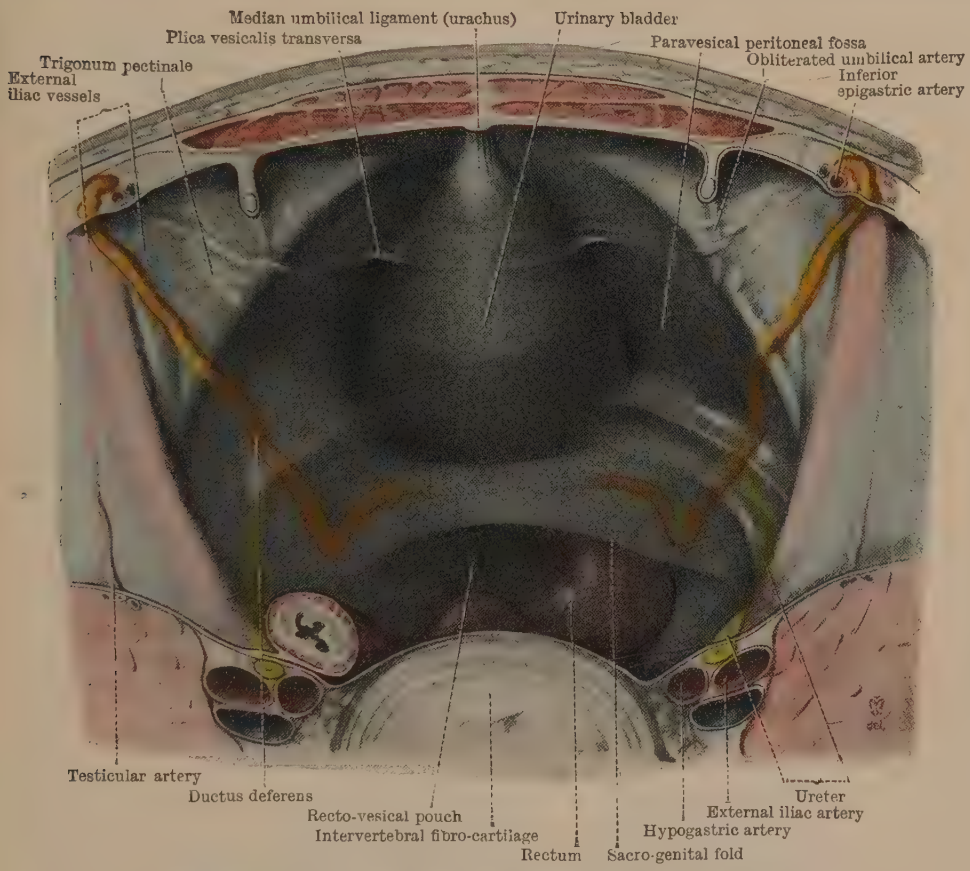

FIG. 983.—VIEW OF THE MALE PELVIS SEEN FROM ABOVE AND BEHIND.
The course of the ductus deferens is well seen.

the pubic tubercle, near which, crossing the medial end of the inguinal ligament, the duct enters the inguinal canal by the subcutaneous inguinal ring (Fig. 991). Of the structures composing the spermatic cord the duct is the most posterior, and it can be distinguished readily, even in the undissected subject, by its hard firm feel, when it is taken between the finger and thumb. In the inguinal canal the ductus deferens is directed laterally, upwards and a little backwards to the abdominal inguinal ring, where, at a point half an inch above the inguinal ligament, and midway between the symphysis pubis and the anterior superior iliac spine, it enters the abdomen. The distance between the point where the cord enters the inguinal canal to the point where it leaves it, to enter the abdomen, is about one and a half inches. While passing from the subcutaneous to the abdominal inguinal ring the ductus deferens, together with the other

structures of the spermatic cord, rests upon the upper grooved surface of the inguinal ligament, and is placed behind the aponeurosis of the external oblique and some of the lower fibres of the internal oblique muscle. From before backwards the duct rests, in the first instance, upon the falx aponeurotica, or conjoined tendon of the internal oblique and transversus abdominis muscles, and more laterally upon the fascia transversalis. Above are some arching fibres of the internal oblique muscle which enter the falx. As the deferent duct leaves the inguinal canal by the abdominal inguinal ring, it turns round the inferior epigastric artery on its lateral and posterior aspect (Fig. 983). Completely changing the direction of its course, the duct now runs for a short distance backwards, medially, and upwards, beneath the peritoneum, to a point one and a half to two inches from the pubic tubercle, where it crosses the pecten of the pubis and enters the pelvis minor.

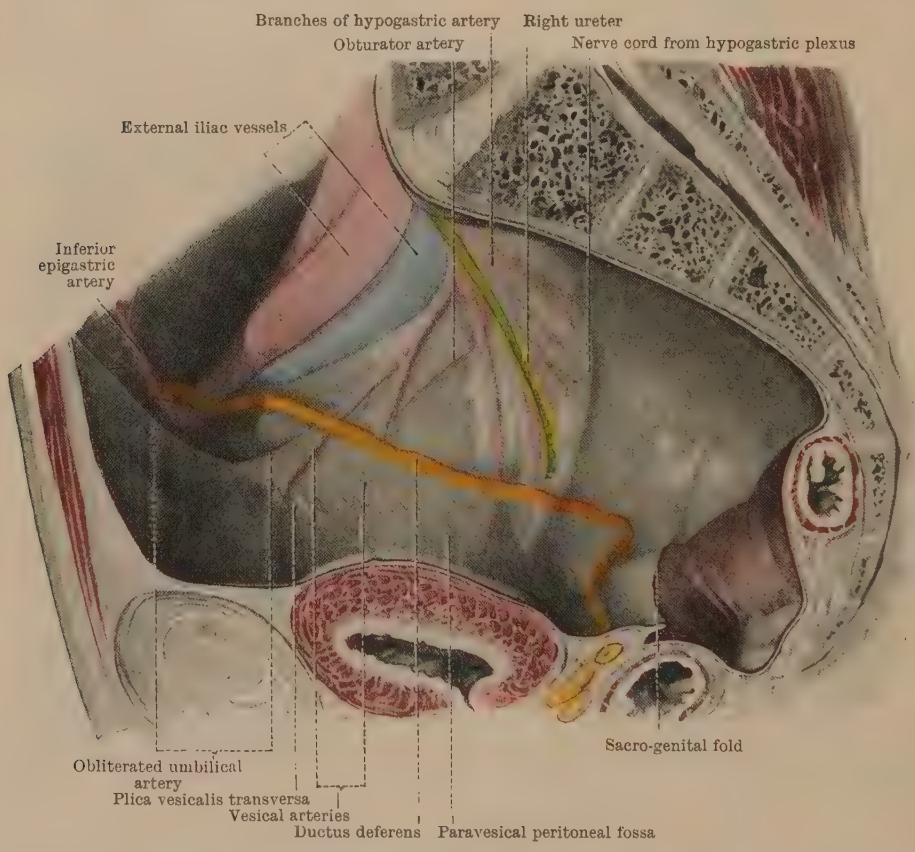

FIG. 984.—MEDIAN SECTION OF THE PELVIS IN AN ADULT MALE.

The coils of small intestine and colon which lay within the pelvis have been lifted out in order to give a view of the side wall of the pelvic cavity.

In this part of its course the duct usually lies at first in front of the external iliac vessels, and then in the floor of a little triangular fossa, the *trigonum pectinale* between these vessels and the pelvic brim (Fig. 983). On the side wall of the pelvis minor the deferent duct is continued backwards, and a little downwards and medially, in the direction of the ischial spine, and lies immediately external to the peritoneum, through which it can usually be seen shining. In the pelvic part of its course the duct crosses on the medial side of (1) the obliterated part of the umbilical artery, (2) the obturator nerve and vessels, (3) the vesical vessels, and (4) the ureter (Fig. 984).

Beyond the ureter the duct takes a somewhat sudden bend, and passes downwards and medially towards the median plane, beneath the peritoneum of the pelvic floor. Reaching the interval between the fundus of the bladder in front and the

rectum behind, the ducts of opposite sides occupy the angle formed between the right and left seminal vesicles (Fig. 987). As they approach one another each duct becomes somewhat tortuous, sacculated and dilated, and assumes a general resemblance in structure to a portion of the seminal vesicle. This dilated part of the deferent duct is termed the **ampulla**. As it turns medially the duct lies a short distance behind the ureter, and immediately in front of the free edge of the (sacro-genital) peritoneal fold which bounds the recto-vesical or (recto-genital) pouch of the peritoneum. Just above the base of the prostate the ductus deferens becomes once more a narrow canal and is joined by the duct of the corresponding seminal vesicle to form the **ejaculatory duct**, which, after a short course downwards, forwards and medially through the prostate, opens into the urethra.

In some cases the ductus deferens crosses the obliterated umbilical artery before it enters the cavity of the pelvis minor; it normally does so in the fœtus (Fig. 988).

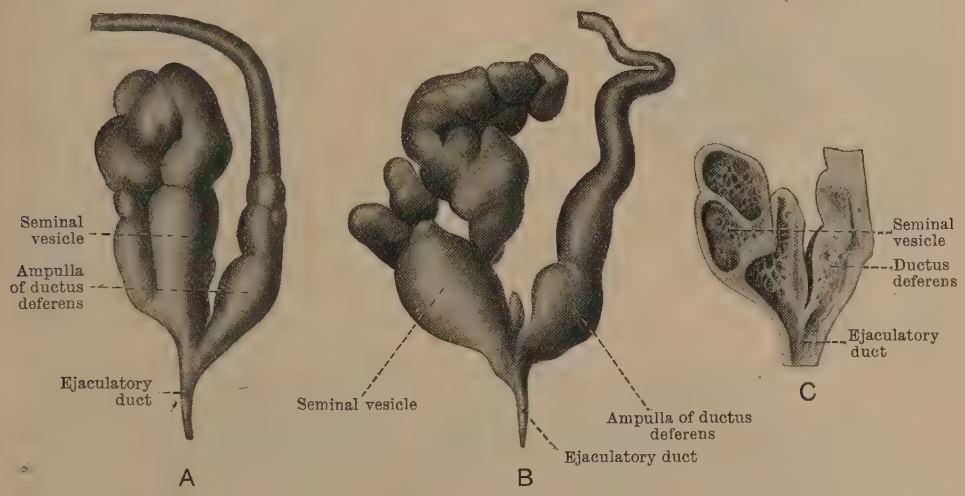

FIG. 985.

A and B. Drawings illustrating the seminal vesicle and the ampulla of the ductus deferens taken from two different subjects.
C. The seminal vesicle and ductus deferens have been cut into to show the pitted structure of their walls.

Ductus Ejaculatorius.—The **ejaculatory duct** is a very slender canal, formed by the union of the ductus deferens with the duct of the corresponding seminal vesicle (Fig. 985). It is less than one inch in length, and lies very close to its fellow of the opposite side as it passes through the prostate behind its median lobe. The ducts open by slit-like apertures into the first part of the urethra, one on each side of the **prostatic utricule.** They are well seen in sections through the upper part of the prostate (Figs. 986 and 997).

The mucous membrane of the duct is thrown into numerous complicated folds, and in connexion with it are a number of remarkable minute diverticula, which are enclosed within the muscular coat of the duct.

VESICULÆ SEMINALES.

The **seminal vesicles** are a pair of hollow sacculated structures placed in front of the rectum and behind the bladder (Fig. 986). Each vesicle is usually about two inches in length, and has its long axis directed downwards, medially, and somewhat forwards. The superior extremity of the vesicle, which is partly covered by peritoneum, is large and rounded, and lies at a considerable distance from the median plane, behind the inferior end of the ureter. It is separated from the rectum by the peritoneum of the recto-vesical or recto-genital pouch. Below the level of the peritoneal cavity the seminal vesicle and rectum are more intimately related. The vesicle tapers towards its inferior end, which is placed close to the

median plane immediately above the prostate. In this position the vesicle becomes constricted to form a short duct, which joins the lateral side of the corresponding ductus deferens at an acute angle. The common duct thus formed is known as the ejaculatory duct. The medial side of each vesicle is related to the ductus deferens, and the lateral side, when the bladder is empty, lies close to the sloping pelvic floor. The seminal vesicles are more intimately related to the wall of the bladder than to that of the rectum. Their superior extremities are, as we have seen, separated from the rectum by a portion of the recto-vesical pouch of peritoneum, and lower down the septum of fascia which intervenes between the seminal vesicles and the rectum is denser than that which separates them from the bladder.

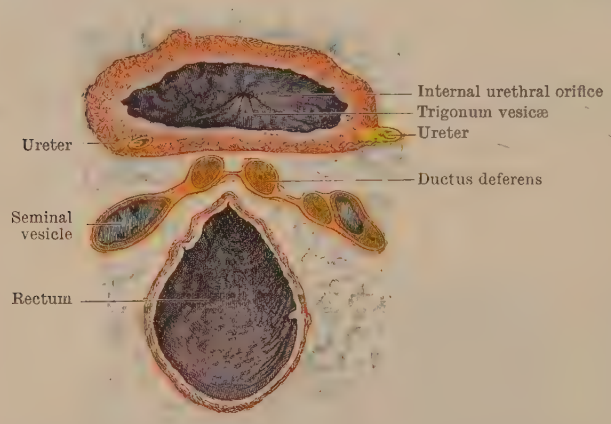

FIG. 986. — HORIZONTAL SECTION THROUGH THE RECTUM AND URINARY BLADDER AT THE LEVEL AT WHICH THE URETERS PIERCE THE BLADDER WALL.

From a specimen in the Surgical Museum, Trinity College, Dublin.

The seminal vesicle often assumes a more vertical position when the bladder is distended; a more horizontal direction when the bladder is empty. Its superior extremity is sometimes found to be curved backwards

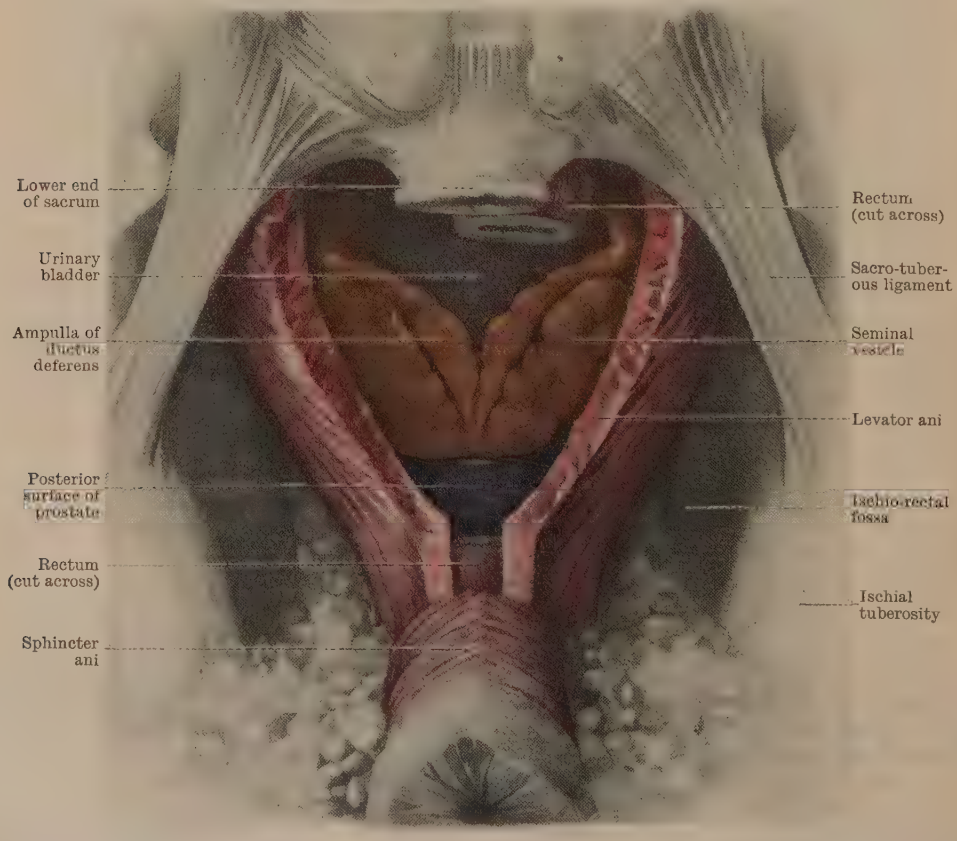

FIG. 987.—DISSECTION TO DISPLAY THE POSTERIOR ASPECT OF THE VESICULÆ SEMINALES, THE AMPULLÆ OF THE DUCTUS DEFERENTES, AND THE PROSTATE. The coccyx and portions of the levatores ani have been removed, also a considerable portion of the rectum.

against the side of the rectum. In some cases the seminal vesicles are much smaller than usual, and may be less than one inch in length. Frequently they are asymmetrical as regards size and shape.

Each seminal vesicle is in reality a tube bent in a tortuous manner on itself, and if the dense connective tissue which envelops it is taken away, the length of the tube when untwisted may be found to be as much as five inches. The tube is closed above, and a variable number of short tortuous branches come off it at different levels. The blind end of the tube usually lies at the superior and lateral extremity of the seminal vesicle, but in some cases the tubular structure is so bent upon itself that the blind terminal part lies against the side of the issuing duct. Their mode of development shows that the seminal vesicles are to be regarded as diverticula of the deferent ducts, from which they originally arise as small pouched outgrowths.

The seminal vesicles are not present in all mammals, and in those in which they do occur their relative size and form vary much. Among the carnivora and marsupials, for instance, the seminal vesicles do not occur; in some other animals, as in the hedgehog, they are relatively of enormous size.

The dense tissue in which the seminal vesicles are embedded contains much unstriped muscle tissue, which sweeps round in the side wall of the recto-vesical pouch. Inferiorly this tissue is attached to the capsule of the prostate. The large veins coming from the prostatic and vesical plexuses are closely related to the seminal vesicles.

Structure of the Ductus Deferens and of the Vesicula Seminalis.—Except near its termination, where it is dilated to form the ampulla, the ductus deferens is a thick-walled tube with relatively a very small lumen. The hard cord-like sensation which it conveys to the touch is due to the thickness and toughness of its wall. Microscopical examination shows that the wall of the ductus deferens is composed of three layers—an outer **adventitious coat** of fibrous connective tissue, an intermediate **muscular coat** and an inner **mucous coat**. The thickness of the wall is due to the great development of the middle or muscular coat, which is composed of an intermediate stratum of circularly and an inner and outer stratum of longitudinally directed unstriped muscular fibres. Of these strata the intermediate is by far the thickest, and forms the chief part of the thickness of the wall of the ductus deferens. The mucous membrane of the duct exhibits a number of slight longitudinal folds and possesses a ciliated epithelium. The ampulla, or terminal part, possesses a much thinner wall, and, as the surface of its mucous membrane has a number of ridges separating depressed areas, the lining of this part of the tube presents a pitted or honeycombed appearance. The wall of the vesicula seminalis resembles that of the ampulla in being thin, and in having a mucous lining with uneven honeycomb-like ridges and depressions. In it the same coats are to be recognised as in the ductus deferens, but the muscular layer is much thinner, and the strata composing it less regularly arranged.

Vessels and Nerves of the Ductus Deferens and of the Vesicula Seminalis.—The deferent duct receives its main arterial supply from the superior or inferior **vesical artery**. The artery to the duct accompanies that structure, supplying it as far as the testis, where it ends by anastomosing with branches of the testicular artery. The seminal vesicle is supplied by the **inferior vesical artery**. The **nerves** of the ductus deferens and vesicula seminalis are derived from the hypogastric plexus. In lower animals the nerves for the seminal vesicles are derived from the nerve roots of the second, third, and fourth lumbar nerves.

Descent of the Testis.

The peculiar course pursued by the ductus deferens in the adult, and the manner in which it is related to the anterior abdominal wall, are rendered clear by a study of the arrangement of the parts in the fœtus. The testes until nearly the end of intra-uterine life are placed in the abdominal cavity. Lying at first on the posterior wall of the abdomen at the level of the upper lumbar vertebræ, and just below the level assumed at this time by the permanent kidney, the testis is held in place by a fold of peritoneum or mesentery, called the **mesorchium**. As growth goes on the testis is found to occupy a lower level in the abdominal cavity; in

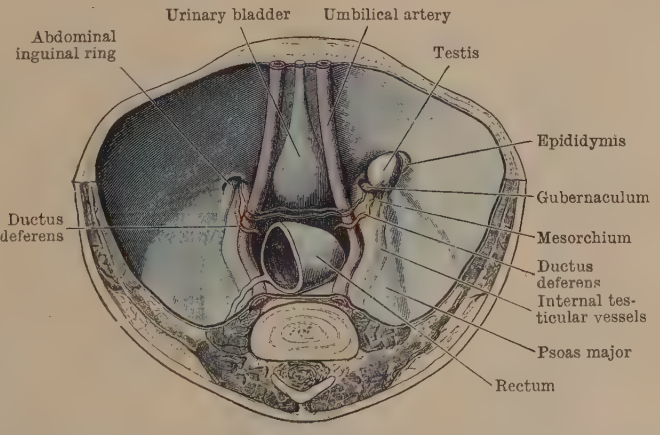

Fig. 988.—View looking from above into the Pelvis and Lower Part of the Abdominal Cavity in a Fœtus of about the Seventh Month.

On the left side, which represents a slightly more advanced condition than the right, the testis has entered the inguinal canal; on the right side the testis is still within the abdominal cavity.

the third month it lies in the iliac fossa, and in the seventh it is situated near the abdominal inguinal ring. Meanwhile a blind pouch or diverticulum of the peritoneal membrane, termed the **processus vaginalis**, has grown downwards and medially through the anterior abdominal wall towards the scrotum, deriving as it goes a covering from each of the layers of the abdominal wall through which it passes. The testis with its mesorchium enters the processus vaginalis and descends within it until the scrotum is reached. At a later stage, the connexion between the part of the processus vaginalis that lies in the scrotum and the peritoneal lining of the abdomen becomes lost by the obliteration of the upper part of the pouch. Thus the part of the processus vaginalis that persists in the scrotum becomes the parietal lamina of the tunica vaginalis; while the visceral lamina of that membrane is the primitive peritoneal covering of the testis and epididymis (Figs. 978, 989).

Often a small fibrous band—the "ligamentum vaginale"—may be found in the adult passing through the inguinal canal and joining the peritoneum superiorly in the region of the abdominal inguinal ring. Sometimes this band is connected below with the tunica vaginalis, but more often it cannot be traced so far downwards. When present it represents the obliterated portion of the processus vaginalis, and is therefore known as the **rudimentum processus vaginalis.**

In rare cases the processus vaginalis may persist after birth as a channel freely open to the abdominal cavity above, or the passage, becoming closed at intervals, may give rise to one or more cysts within the coverings of the spermatic cord.

It sometimes happens that the descent of the testis is arrested, and then, either failing to enter the processus vaginalis, the testis remains within the abdominal cavity, or entering the processus vaginalis, it fails to reach the scrotum, and lies in the inguinal canal. The term "cryptorchism" is frequently applied to such cases.

In connexion with the descent of the testis a remarkable cord-like structure—the **gubernaculum testis** [Hunteri]—must be mentioned. The gubernaculum arises for the most part within a peritoneal fold which, at an early time in the development of the fœtus, may be seen stretching from the inguinal region to the Wolffian duct (future duct of the testis) and inferior end of the mesonephros or primitive kidney. This peritoneal fold, termed the *plica inguinalis* (or plica inguino-mesonephrica), is joined from above by a less marked fold (the plica testis inferior) which extends downwards from the inferior end of the testis, which, at this time, is situated in the abdomen close to the medial aspect of the mesonephros. Within both these folds smooth muscular and fibrous tissue arise and give origin to a continuous band, or ligament—the gubernaculum testis. The gubernaculum is therefore to be regarded as originally composed of two portions—a lower part developed within the plica inguinalis, and an upper part formed within the plica testis inferior. It is interesting to note that in the female the representatives of these two parts of the gubernaculum remain separate throughout life, and constitute the round ligament of the uterus and the ligament of the ovary. The gubernaculum, when it is at its greatest development (about the sixth month), is rounded and cord-like, and is attached above to the lower end of the testis, while inferiorly it is fixed near the inguinal region. In the lower part of its course it is closely related to, and is partly covered by, the peritoneum of the processus vaginalis. Striped muscular fibres are present in the lower part of the gubernaculum, and have their origin from the muscles of the inguinal part of the anterior abdominal wall. As the testis enters the processus vaginalis the gubernaculum atrophies, but at birth a short part of the gubernaculum may still be found passing downwards towards the inferior part of the scrotum and lying below the level of the tunica vaginalis. It is considered by some anatomists that the movement downwards of the testis may be partly due to a pull caused by the shrinking of the gubernaculum as it atrophies.

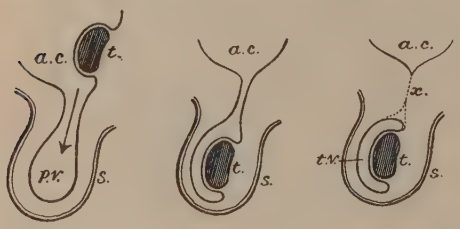

FIG. 989.—DIAGRAM to illustrate the descent of the testis and the manner in which the tunica vaginalis is derived.

a.c. Abdominal cavity.
p.v. Processus vaginalis.
t. Testis.
s. Scrotum.
t.v. Tunica vaginalis.
x. Rudimentum processus vaginalis.

In some mammals, such as the elephant, the testes remain permanently within the abdominal cavity; while in others, such as the rabbit and the hedgehog, the peritoneal pouches remain widely open throughout life, and the testes are periodically withdrawn into the abdomen.

Funiculus Spermaticus (Spermatic Cord).

The testis in its course downwards through the abdominal wall into the scrotum takes with it its duct, its blood and lymph vessels and nerves. All these lie together in the inguinal canal as they traverse the abdominal wall, and when they leave the canal by the subcutaneous inguinal ring they extend downwards to the posterior border of the testis. The deferent duct, the testicular vessels, and the nerves and lymphatics of the testis loosely connected together, form the **funiculus spermaticus**, or spermatic cord. At the abdominal inguinal ring its constituent parts separate from one another, and the cord may therefore be considered to extend from the abdominal inguinal ring to the posterior border of the testis. The structures which form the spermatic cord are enclosed within a number of coverings derived from the layers of the anterior abdominal wall, and these, when the constituents of the cord reach the posterior border of the testis, surround the tunica vaginalis, and so form a part of the wall of the scrotum.

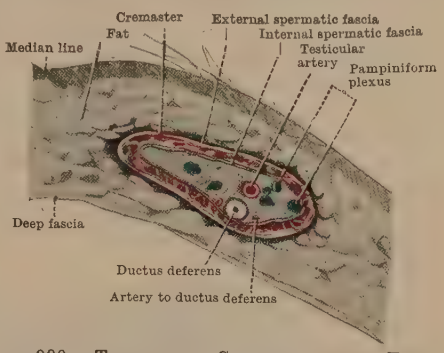

Fig. 990.—Transverse Section of the Funiculus Spermaticus, or Spermatic Cord, just below the Subcutaneous Inguinal Ring.

The sheaths or coverings of the cord derived from the abdominal wall are three in number, and are named external spermatic fascia, cremasteric fascia, and internal spermatic fascia. The *external spermatic fascia* is the most superficial of the three sheaths, and is derived from the aponeurosis of the external oblique muscle, with which it is continuous round the margins of the subcutaneous inguinal ring. The *cremasteric fascia* consists partly of muscular fibres derived from the lower part of the internal oblique muscle, and partly of delicate connective tissue. The muscular fibres constitute the **cremaster** muscle and, passing down over the funiculus, form a series of loops round the testis and tunica vaginalis. The *internal spermatic fascia* is derived from the fascia transversalis of the abdomen. It passes downwards as a continuous sheath over the cord, and encloses its various structures, together with a certain amount of areolar tissue derived from the subperitoneal tissue of the abdominal wall and some smooth muscle fibres.

A section through the spermatic cord as it leaves the superficial inguinal ring shows the coverings loosely surrounding the constituents of the cord, namely the ductus deferens, the testicular artery, the pampiniform plexus of veins, the nerves and lymphatics of the testis. In addition to these structures, the artery to the ductus deferens, the external spermatic branch of the inferior epigastric artery, and a branch of the genito-femoral nerve are included in the structures forming the spermatic cord.

Scrotum.

The **scrotum**, in which the testes are placed, varies much in appearance in different subjects, and even in the same individual at different times. As the result of cold or of exercise, the wall of the scrotum becomes contracted and firm, and the skin covering it wrinkled; at other times the wall may be relaxed and flaccid, the scrotum then assuming the appearance of a pendulous bag. The left side of the scrotum reaches to a lower level than the right, in correspondence with the lower level of the testis on that side of the body. The skin covering the scrotum is of a darker colour than the general skin of the body, and is covered with hair. It is marked in the median plane by the **raphe scroti**, which is continued backwards towards the anus, and forwards on to the urethral surface of the penis. The difference in the appearance of the scrotum at different times is due to the amount of contraction or relaxation of a layer of muscular fibres, constituting the **dartos tunic**, situated in the superficial fascia. When this muscular layer is contracted, the scrotum becomes smaller and somewhat globular, and the skin is thrown into folds or wrinkles called rugæ; when it is relaxed, the scrotum is flaccid and pendulous, and the skin becomes more

smooth and even. The layer of fascia which contains the smooth muscle fibres can be shown to be continuous superiorly with the superficial fascia of the penis, and with the deep layer of the superficial fascia of the abdomen, and to be attached laterally to the bones forming the pubic arch. The muscle fibres are arranged in a thick layer of interlacing bundles, and many of the deeper fibres are continued into the **septum scroti**, which divides the scrotum into two cavities, one for each testis. The wall of each of these cavities is formed by the corresponding tunica vaginalis, internal spermatic fascia, cremasteric fascia, and external spermatic fascia; while the skin, the superficial fascia, and the superficial part of the dartos muscle form coverings which are common to the whole scrotum, and enclose both cavities. The layer of tissue immediately beneath the dartos tunic is made up of exceedingly loose and easily stretched areolar connective tissue, and in it, as throughout in the superficial fascia of the scrotum, there is an entire absence of fat.

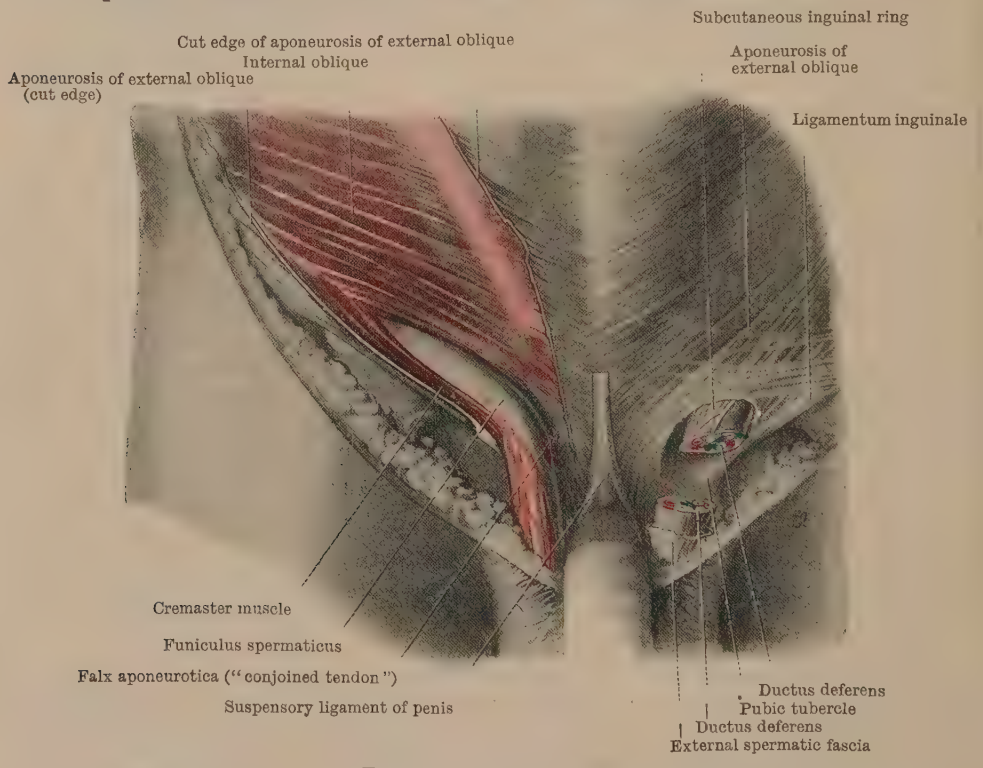

FIG. 991.—DISSECTION TO SHOW THE FUNICULUS SPERMATICUS AS IT ISSUES FROM THE SUBCUTANEOUS INGUINAL RING. On the right-hand side of the figure the funiculus has been cut across, and the structures composing it are seen in section. On the left-hand side of the figure the external oblique muscle has been removed (A. M. Patterson).

The scrotum in the fœtus contains no cavity, but, like the labia majora in the female, it is composed entirely of vascular connective tissue.

The scrotum receives its **vascular supply** on each side from the posterior scrotal branches of the internal pudendal artery, which reach it from behind, and from the external pudendal branches of the femoral artery, which reach its upper and anterior part.

The **nerves** of the scrotum are derived on each side from the posterior scrotal branches of the pudendal nerve, from the perineal branch of the posterior cutaneous nerve of the thigh, and from the ilio-inguinal nerve. The branches from the pudendal and posterior cutaneous nerves reach the scrotum from behind, while the ilio-inguinal supplies its upper and anterior part. The nerve fibres for the dartos muscle fibres are believed to have their origin from the hypogastric plexus.

PENIS.

The **penis** is composed chiefly of erectile tissue, and is traversed by the canal of the urethra. The surface nearest to which the canal of the urethra lies is called the **urethral surface**; the opposite and more extensive aspect is the **dorsum penis**. The erectile tissue is for the most part disposed in three

longitudinal columns, which in the body of the organ are placed side by side, while at the root of the penis they separate from one another, and become attached to the inferior fascia of the uro-genital diaphragm and to the pubic arch. Two of these masses of erectile tissue, placed one on each side of the median plane, and forming the dorsum and sides of the penis, are called the **corpora cavernosa penis**, while the third, which is situated in the median plane near the urethral surface, is called the **corpus cavernosum urethræ**. The corpus cavernosum urethræ is the part of the penis which is traversed by the urethra, and it is considerably smaller than the corpora cavernosa penis, which form the chief bulk of the organ (Fig. 992).

In the **body of the penis**, each corpus cavernosum penis is placed close to the median plane, and presents a rounded surface, except where it is flattened by contact with its fellow of the opposite side. The corpora cavernosa penis are separated on the dorsal surface by a shallow groove, and on the urethral aspect by a deeper and wider furrow, in which lies the corpus cavernosum urethræ (Fig. 993). Towards the distal end of the penis the corpus cavernosum urethræ appears to expand, and, spreading towards the dorsal surface of the organ, it forms a kind of conical cap, the **glans penis**, which covers over the blunt rounded termination of the corpora cavernosa penis. The prominent margin of the glans, called the **corona glandis**, projects dorsally and laterally beyond the extremities of the corpora cavernosa penis. The glans is traversed by the terminal part of the urethra, which ends near the summit of the glans in a slit-like opening, the **external urethral orifice**. The united corpora cavernosa penis end in a blunt conical extremity, the apex of which is received into a hollow in the base of the glans. The skin covering the body of the penis is thin, delicate, and freely movable, and, except near the root of the organ, is free from hairs; on the urethral aspect of the penis the skin is marked by a median raphe, continuous with the raphe of the scrotum. Traced towards the base of the glans, the skin forms a free fold called the **præputium**, or prepuce, which overlaps the glans to a variable extent. From the deep surface of the prepuce the skin is reflected on to the terminal part of the penis, along a line just proximal to the corona glandis, and is continued over the entire glans to the external urethral orifice. A small median fold, the **frenulum præputii**, passes to the deep surface of the prepuce from a point immediately below the external urethral orifice. The skin covering the glans is firmly attached to the underlying erectile tissue, and here, as well as on the deep surface of the prepuce, it presents some resemblance to mucous membrane.

The secretion, known as the **smegma præputii**, which tends to collect beneath the prepuce has its source in the desquamated and broken-down epithelial cells derived from the surface of the glans and prepuce.

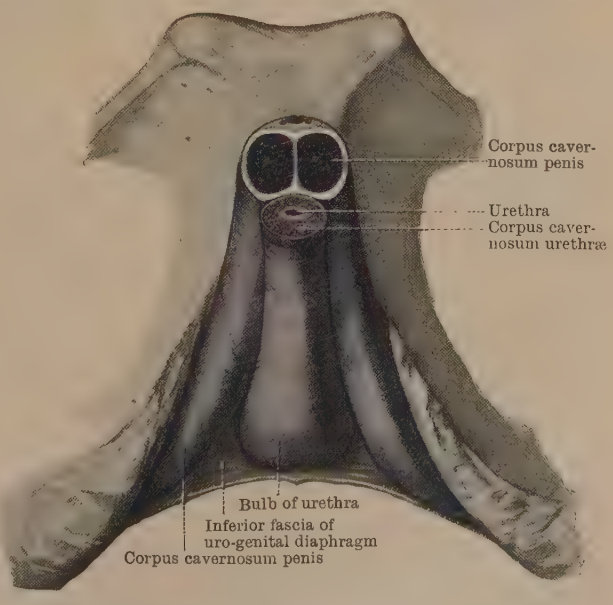

FIG. 992.—STRUCTURES COMPOSING THE RADIX PENIS.
The corpus penis is seen in section.

At the **root of the penis** the three component parts of the organ separate from one another (Fig. 992). The corpora cavernosa penis, diverging laterally, at first become somewhat swollen, and then, gradually

tapering, gain a firm, fibrous attachment to the periosteum on the medial surface of the pubic arch. These diverging parts of the corpora cavernosa are called the **crura penis**, and each is covered by the corresponding ischio-cavernosus muscle. The corpus cavernosum urethræ lying between the crura becomes enlarged, and forms a somewhat spherical mass which receives the name **bulbus urethræ**. The bulb varies much in size in different individuals, and is attached to the under surface of the inferior fascia of the uro-genital diaphragm, against which it rests. The posterior part and under surface of the bulb usually show a median notch or groove—an indication that the bulb is originally composed of two symmetrical portions, which during development have become fused in the median plane. These two portions are best seen in subjects whose tissues have been hardened by intravascular injection. A slightly marked median septum, situated within the bulb tissue, indicates on a deeper plane the line along which fusion has taken place. The canal of the urethra, piercing the inferior fascia of the uro-genital diaphragm, enters the bulb obliquely a short distance in front of its posterior extremity (Fig. 995). Covering the superficial surface of the bulb is the bulbo-cavernosus muscle.

A somewhat triangular band of strong fibrous tissue, called the **suspensory ligament of the penis**, is attached to the front of the symphysis pubis, and extends to the fibrous capsule of the penis, with which it becomes continuous (Fig. 991).

Structure of the Penis.—Each corpus cavernosum penis is enclosed by a dense white fibrous coat—**tunica albuginea**, which, fusing with the corresponding coat of the opposite side, forms the median **septum** of the penis. The septum is very incomplete, especially near the terminal part of the penis, where it is interrupted by a number of nearly parallel slit-like

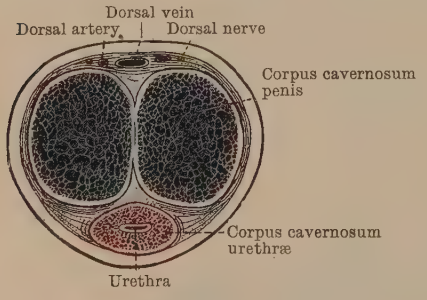

Fig. 993.—Transverse Section through the Body of the Penis.

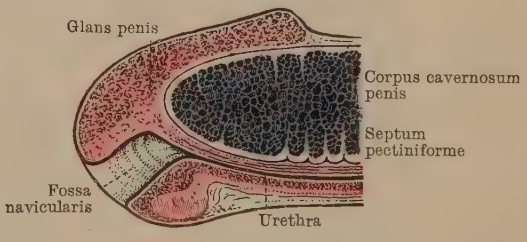

Fig. 994.—A Longitudinal Section of the Terminal Portion of the Penis.

perforations; hence the term "septum pectiniforme" is often applied to it (Figs. 993 and 994). Through these openings the erectile tissue of the corpora cavernosa of opposite sides is continuous.

The fibrous coat contains some elastic fibres, and may be divided into an outer layer of longitudinally directed fibres and an inner layer of circular fibres, some of which latter are continued into the septum. Numerous fibrous strands, called **trabeculæ**, proceed from the deep surface of the tunica albuginea, and stretching across the interior of the corpus cavernosum, form a fine sponge-like framework whose interspaces communicate freely with one another, and are filled with blood. These blood-containing spaces lead directly into the veins of the penis, and, like the veins, have a lining of flat endothelial cells. The size of the penis varies with the amount of blood in this cavernous tissue. The structure of the corpus cavernosum urethræ resembles that of the corpora cavernosa penis, but the fibrous coat is much thinner and more elastic, and the trabeculæ are finer (Fig. 993).

The glans penis is also composed of cavernous tissue which communicates by a rich venous plexus with the corpus cavernosum urethræ. No strongly marked tunica albuginea is present, and the erectile tissue is practically bounded by the firmly adherent skin. Surrounding the urethra, which in this part of the penis is represented by a laterally compressed slit-like passage, is a mass of fibro-elastic tissue which forms a kind of median septum within the glans. This septum is continued backwards to join the sheath of the conical end of the corpora cavernosa, and ventrally it gives attachment to the frenulum of the prepuce. It imperfectly divides the erectile tissue of the glans into right and left portions, which, however, freely communicate dorsally. From the septum, trabeculæ pass out in all directions into the tissue of the glans.

Loosely surrounding the corpora cavernosa penis and the corpus cavernosum urethræ is a fibrous sheath containing numerous elastic tissue fibres. This sheath is termed the *fascia penis*, and reaches as far as the base of the glans, where it becomes fixed to the floor of the groove limited by the corona of the glans. In its proximal part the sheath gives insertion to many of the fibres of the bulbo-cavernosus and ischio-cavernosus muscles.

Superficial to the fascia penis is a layer of extremely lax areolar tissue, and more superficial still is a prolongation of the dartos tunic of the scrotum, covered by the delicate skin of the penis. Numerous sebaceous glands are present in the skin, especially on the urethral aspect of the penis.

In some mammals, such as the walrus, dog, bear, and baboon, a bone called the **os penis** is developed in the septum which intervenes between the corpora cavernosa penis.

The penis receives its **arterial supply** from branches of the internal pudendal artery. The erectile tissue of the corpora cavernosa penis is supplied chiefly by the deep arteries of the penis, while that of the corpus cavernosum urethræ receives its arterial supply from the artery to the bulb. Branches of the dorsal artery of the penis piercing the fibrous coat of the corpora cavernosa penis furnish additional twigs to the erectile tissue of these structures. The glans receives its chief blood-supply from branches of the dorsal artery. The small branches of these arteries run in the trabeculæ of the erectile tissue, and the capillaries, into which they lead, open directly into the cavernous venous spaces. As they lie in the finer trabeculæ the smaller branches often present a peculiar twisted appearance, and hence the name **arteriæ helicinæ** is sometimes applied to them.

The **veins** with which the cavernous spaces communicate carry the blood, for the most part, either directly into the pudendal plexus, or into the dorsal vein and so to the pudendal plexus. The dorsal vein of the penis begins in tributaries from the glans and prepuce, and lies in the groove between the corpora cavernosa penis as it ascends to pass beneath the arcuate ligament of the pubis to join the pudendal plexus. On each side of it lies the dorsal artery, and still farther from the median plane lies the dorsal nerve (Fig. 993).

The **lymph-vessels** of the penis are arranged in a deep and superficial series, and end in the medial glands of the inguinal group of lymph-glands.

The **nerve-supply** of the penis is derived from the pudendal nerve (2nd, 3rd, and 4th sacral nerves), and from the hypogastric and pelvic plexuses. The branches of the pudendal are the dorsal nerve of the penis, and branches from the perineal nerves. These supply the cutaneous structures of the penis, while the sympathetic filaments from the hypogastric and pelvic plexuses, which reach the penis through the prostatic nerve plexus, end in the erectile tissue.

PROSTATA.

The **prostate** is a partly glandular, partly muscular organ of a dark brown-red colour which surrounds the beginning of the urethra in the male. It lies within the pelvis behind the symphysis pubis, and is enclosed by a dense sheath derived from the pelvic fascia. Through the various connexions of this sheath the prostate is firmly fixed within the pelvic cavity. The ejaculatory ducts traverse the prostate in their course downwards and forwards to join the urethra as it descends through the gland (Fig. 998). The size of the prostate varies considerably in different individuals, but its transverse, or longest, diameter is usually from one and a quarter to one and a half inches; its antero-posterior diameter about three-quarters of an inch; and its vertical diameter about one and a quarter inches. Superficially the prostate is separated from the bladder by deep wide lateral grooves directed downwards and forwards, and by a narrow posterior groove which is horizontal.

In connexion with the prostate we describe an apex which is directed downwards, a base looking upwards, a posterior, and two lateral surfaces. The general outline of the organ has been often compared with that of a Spanish chestnut. The upper surface, or *base of the prostate*, is directed upwards against the inferior aspect of the bladder, in the neighbourhood of its urethral opening. The greater part of this surface is structurally continuous with the bladder wall; only a narrow portion remains free on each side and forms the lower limit of the deep groove which marks the separation of the bladder and prostate (Fig. 971). The *lateral surfaces* of the prostate are convex and prominent, especially in their posterior and upper portions, and rest against the fascia covering the levatores ani muscles. They are directed for the most part laterally, downwards, and somewhat forwards, and meet together in front in a rounded anterior border, sometimes called the "anterior surface" of the prostate. Posteriorly the prostate presents a flattened somewhat triangular *posterior surface*, directed backwards and downwards against the anterior wall of the rectum, through which it may be felt in the living subject. This flattened posterior surface is separated on each side from the lateral surfaces by a rounded border which, beginning above at the prominent lateral part of the prostate, ends below at the apex of the organ. The apex of the prostate points downwards, and is in relation to the sphincter urethræ membranaceæ

muscle, from which it is separated by the superior fascia of the uro-genital diaphragm. From the apex the rounded anterior border, which separates the lateral surfaces, passes upwards in the median plane behind the symphysis pubis and retro-pubic pad of fat. This border is interrupted in its lowest part by the passage of the urethra.

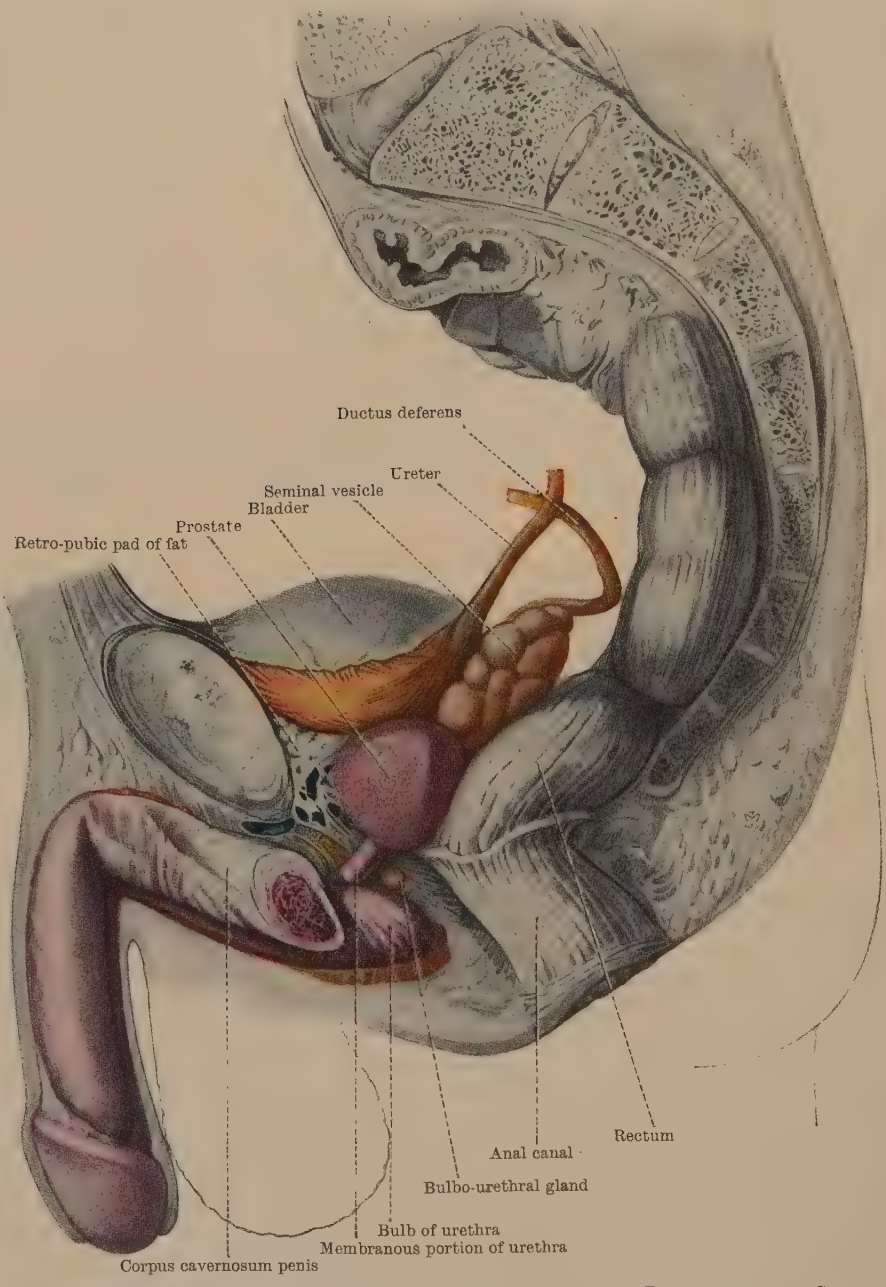

FIG. 995.—DISSECTION OF THE MALE PELVIC ORGANS AND OF THE PENIS, FROM THE SIDE

The dorsal vein of the penis and the pudendal venous plexus are coloured blue.

When the thick fibrous sheath formed by the pelvic fascia is stripped off the prostate the organ has a more rounded outline, and the surfaces just described are not so clearly defined. The anterior border may now appear to be rather a surface than a border, and the antero-posterior diameter of the whole organ is considerably reduced.

The urethra enters the prostate at a point near the middle of its upper surface or base, and leaves it at a point situated on its anterior border, just above and in front of the apex. As it descends, the urethra describes a curve which is concave forwards, and in median section it is seen to lie, on the whole, nearer to the posterior surface than to the anterior border of the gland.

The ejaculatory ducts, entering a slit-like interval, or hilum, situated just in front of the border which separates the base from the posterior surface of the prostate, run downwards, medially, and forwards, to open into the prostatic portion of the urethra very close to one another.

The somewhat wedge-shaped portion of the prostate, which lies between these ducts and the posterior aspect of the urethra, receives the name of *middle lobe* (Fig. 997). It projects upwards against the bladder, and is continuous with the part of the bladder wall lying immediately behind the urethral orifice. When hypertrophied, as it often is in old people, the middle lobe of the prostate may cause a considerable elevation in the cavity of the bladder, which possesses considerable surgical interest (p. 1265), and to which the term uvula vesicæ is applied.

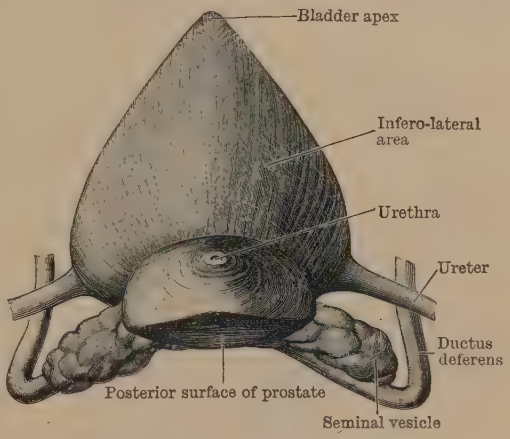

FIG. 996.—PROSTATE, URINARY BLADDER, AND SEMINAL VESICLES SEEN FROM BELOW.

Drawn from a specimen hardened *in situ*. The lateral surfaces of the prostate are seen one on each side of the urethra and in front of the posterior surface.

The rest of the prostate is described as being composed of two large *lateral lobes*, which are, however, not marked off from one another superficially.

In front of the prostate, between it and the pubis, is the rich venous pudendal plexus, in which the dorsal vein of the penis terminates. This plexus is continued backwards, on each side, round the lateral aspect of the prostate, and joins the large thin-walled veins which are collected for the most part in the deep sulcus between the bladder wall and the prostate, and form the prostatico-vesical plexus. Most of the veins forming this plexus lie partly within and partly outside the dense fibrous sheath of the prostate, which is derived from the pelvic fascia (Fig. 997).

Fibrous Sheath of the Prostate.—The **sheath of the prostate** is formed by the pelvic fascia, and closely invests the gland on its lateral and posterior aspects. Inferiorly at the apex of the prostate the sheath becomes continuous with the superior fascia of the uro-genital diaphragm, which lies above the sphincter urethræ membranaceæ muscle, and is attached to the pubic arch. In front two thickened bands pass forwards from the anterior aspect of the sheath, one on each side of the median plane, to reach the back of the lower part of the pubis, where they are attached to the periosteum. These constitute the pubo-prostatic ligaments, and contain smooth muscle fibres, as well as dense connective tissue. Some of the muscle fibres in connexion with the pubo-prostatic ligaments, passing upwards as well as backwards, gain the bladder wall, and are spoken of as the pubo-vesical muscles. Between the right and left pubo-prostatic ligaments there is a shallow fossa, or depression, the floor of which is formed by a thin layer of fascia connecting the anterior aspect of the sheath of the prostate with the back of the pubis. This layer forms a part of the wall of the retro-pubic space which lies in front of the prostate and below the bladder (Fig. 995). Below the pubo-prostatic ligaments the medial edges of the levatores ani muscles pass medially and almost meet together in front of the apex of the prostate. When followed backwards, the medial edges of these muscles are seen to embrace the apex of the prostate.

On each side the lateral aspect of the sheath of the prostate is continuous with the strong fascia which covers the pelvic surface of the levator ani muscle. When the fibrous sheath of the prostate is traced upwards beyond the level of the upper margin of the gland it becomes thinned out and disappears. Posteriorly the upward prolongation of the sheath is continuous with the fascial layers which enclose the ampullæ of the deferent ducts and the seminal vesicles, and it is adherent to the peritoneum of the recto-vesical pouch. In this position it is often spoken of as the recto-vesical fascia.

Structure of the Prostate.—Beneath the fibrous sheath of the gland the superficial part of the prostate is seen to be largely composed of matted interlacing bundles of smooth muscle and

connective tissue fibres, which form a kind of capsule for the deeper parts of the organ. This **capsule** is not sharply defined, but from its deep aspect fibrous and muscular strands pass inwards, converging towards the posterior wall of the urethra, to become continuous with the mass of smooth muscular tissue which surrounds this canal as it traverses the prostate. The somewhat radially arranged strands divide the prostate into a number of incompletely defined lobules, of which there appear to be about fifty. The yellowish-coloured glandular tissue which forms the lobules is composed of minute, slightly branched tubules, the walls of which in certain places show numerous saccular dilatations. In the upper portion of the gland the tubules are slightly dilated and shorter than in the lower part, where they are longer and more convoluted. The glandular tubules lead into the minute prostatic ducts, which open into the urethral canal as it traverses the prostate. The **prostatic ducts** number about twenty or thirty, and open for the most part into a groove, the **prostatic sinus**, on each side of the median elevation, or **crista urethralis**, in the posterior wall of the urethra (Fig. 999).

The bulk of the glandular tissue is situated at the sides of and behind the urethra. In front of the upper part of the prostatic portion of the urethra there is a mass of smooth muscular fibres, which is continued upwards and backwards on the sides of the urethra to form a part of the "sphincter vesicæ." At a lower level striped muscular tissue, which is continuous with the deep part of the sphincter urethræ membranaceæ muscle, occupies a position in front of the urethral canal.

The muscular tissue of the prostate is to be regarded as the thickened muscular layer of the wall of the urethra, broken up and invaded by the prostatic glands which arise and are developed from the lining layer of the canal during embryonic life.

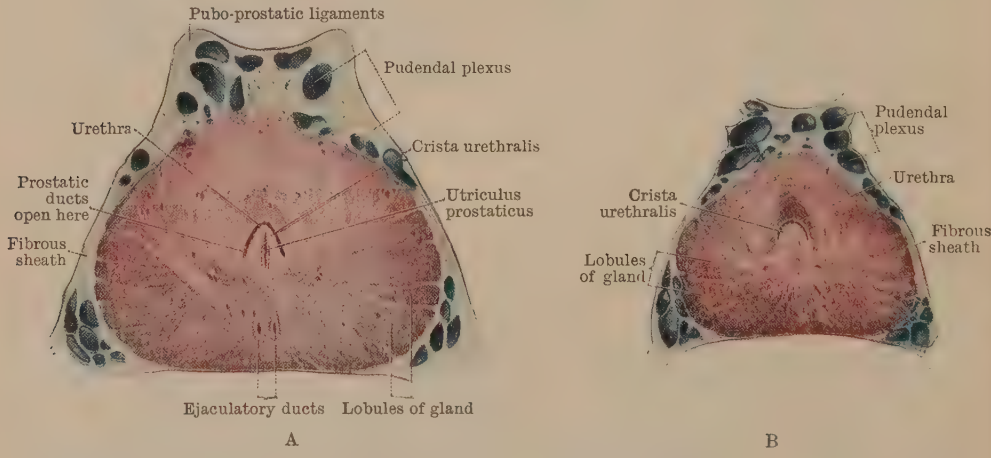

FIG. 997, A and B.—HORIZONTAL SECTIONS THROUGH THE PROSTATE. Section A lies at a higher level than B.

In old age the prostate frequently undergoes a hypertrophy, which may affect chiefly the glandular tissue, or the entire organ. Not infrequently calcareous concretions are found embedded in the prostate.

The prostate receives its **arterial supply** from branches of the hæmorrhoidal and inferior vesical arteries, while the large plexus of **veins**—the pudendal plexus—which surrounds it, and into which the veins of the penis open, communicates with the vesical plexus, and drains into the hypogastric veins. In old people the veins of the prostate usually become much enlarged.

The **nerves** of the prostate are derived from the pelvic plexus.

GLANDULÆ BULBO-URETHRALES.

The **bulbo-urethral** or **Cowper's glands** are a pair of small bodies placed in relation to the second, or membranous, part of the urethra. They are each about the size of a pea, and are of a yellowish-brown colour. Situated in the space between the two fasciæ of the uro-genital diaphragm, they lie below the level of the apex of the prostate, and above that of the bulbus urethræ (Figs. 995 and 999). Each gland is made up of a number of closely applied lobes or lobules, and is of the compound racemose type. The ductules of the gland unite to form a single **excretory duct**, which pierces the bulbus urethræ, and, after a relatively long course, ends by opening into the cavernous portion of the urethra by a minute aperture. The secreting acini are lined with columnar epithelium.

The glands receive their arterial supply from the artery to the bulb.

In old age these glands are often difficult to find without a microscopic examination

URETHRA VIRILIS.

The **urethra** in the male is a channel of about eight inches in length leading from the bladder to the external urethral orifice at the extremity of the glans penis. The canal serves not only for the passage of urine, but it also affords an exit for the seminal products, which enter by the ejaculatory ducts, and for the secretion of the prostatic and bulbo-urethral glands. In addition, numerous minute **urethral glands** pour their secretion into the urethra.

As it passes from the internal urethral orifice to its external opening, the urethra describes a somewhat ∫ shaped course, and it is customary to divide it into certain sections, which have received distinctive names. The first part of the urethra lies within the pelvic cavity, and has a somewhat vertical course as it traverses the prostate. Turning more forwards, the urethra passes below the pubic arch, and pierces the fibrous layers which form the pelvic wall in this region. Leaving the pelvis minor, the canal enters the bulbus urethræ, where the latter is attached to the inferior fascia of the uro-genital diaphragm, and throughout the rest of its course it lies in the erectile tissue of the corpus cavernosum urethræ and of the glans penis. The part of the urethra which lies embedded in the prostate is called the **pars prostatica**; the short part which pierces the pelvic wall is called the **pars membranacea**, and the part surrounded by the corpus cavernosum urethræ receives the name of **pars cavernosa**. Of these three sections of the urethra the cavernous portion is much the longest, and the membranous is the shortest.

The **prostatic part** of the male urethra descends through the prostate from the base towards the apex, describing a slight curve which is concave forwards. It is about one inch in length, and is narrower above and below than in its middle portion, which is, indeed, the widest part of the whole urethral canal. Except while fluid is passing, the canal is contracted, and the mucous membrane of the anterior and posterior walls is in contact, and thrown into a series of longitudinal folds. When distended, the middle, or widest part of the canal, may normally have a diameter of about one-third of an inch. The posterior wall, often termed the "floor" of the prostatic urethra, presents a distinct median ridge or elevation called the **crista urethralis** (Fig. 999). This projects forwards into the urethra to such an extent that the canal in transverse section presents a somewhat crescentic outline (Fig. 997). The groove on each side of the crista urethralis is known as the **prostatic sinus**, and into it the numerous ducts of the prostatic glands open by minute apertures. Some few ducts from the middle part of the gland open nearer the median plane, on the sides of the urethral crest. On the summit of the crista urethralis is a small slit-like opening which leads backwards and upwards for a distance of about a quarter of an inch, as a blind pouch, in the substance of the prostate. This little cavity is known as the **prostatic utricle**, and represents the fused caudal ends of the Müllerian ducts, from which the uterus and vagina of the female are developed. On each side of the mouth of the utricle is the much more minute opening of the ejaculatory duct. When traced upwards towards the bladder, the urethral crest, diminishing in height, becomes indistinct, but it can often be traced as a slight median ridge as far as the uvula vesicæ. When followed in the opposite direction the ridge becomes less marked, and can be followed on the urethral wall into the membranous portion of the canal, where it divides into a pair of inconspicuous folds or elevations, which gradually fade out into the urethral wall (Fig. 999).

The curvature and, to a less degree, the length of the prostatic urethra depends upon the amount of distension of the bladder and of the rectum (compare Figs. 967 and 968).

The second or **membranous portion** of the urethra leads downwards and forwards from the apex of the prostate to the bulbus urethræ, and is the shortest and narrowest of the three subdivisions of the canal, its length being somewhat less than half an inch. It begins at the superior fascia of the uro-genital diaphragm, a layer of pelvic fascia which lies above the sphincter urethræ membranaceæ

muscle. Here it is continuous with the prostatic portion of the urethra. It ends, having pierced the inferior fascia of the uro-genital diaphragm, by becoming continuous with the cavernous portion of the urethra. Placed in front of the anal canal, it lies about one inch behind and below the arcuate ligament of the pubis. It is surrounded by fibres of the sphincter urethræ membranaceæ muscle,

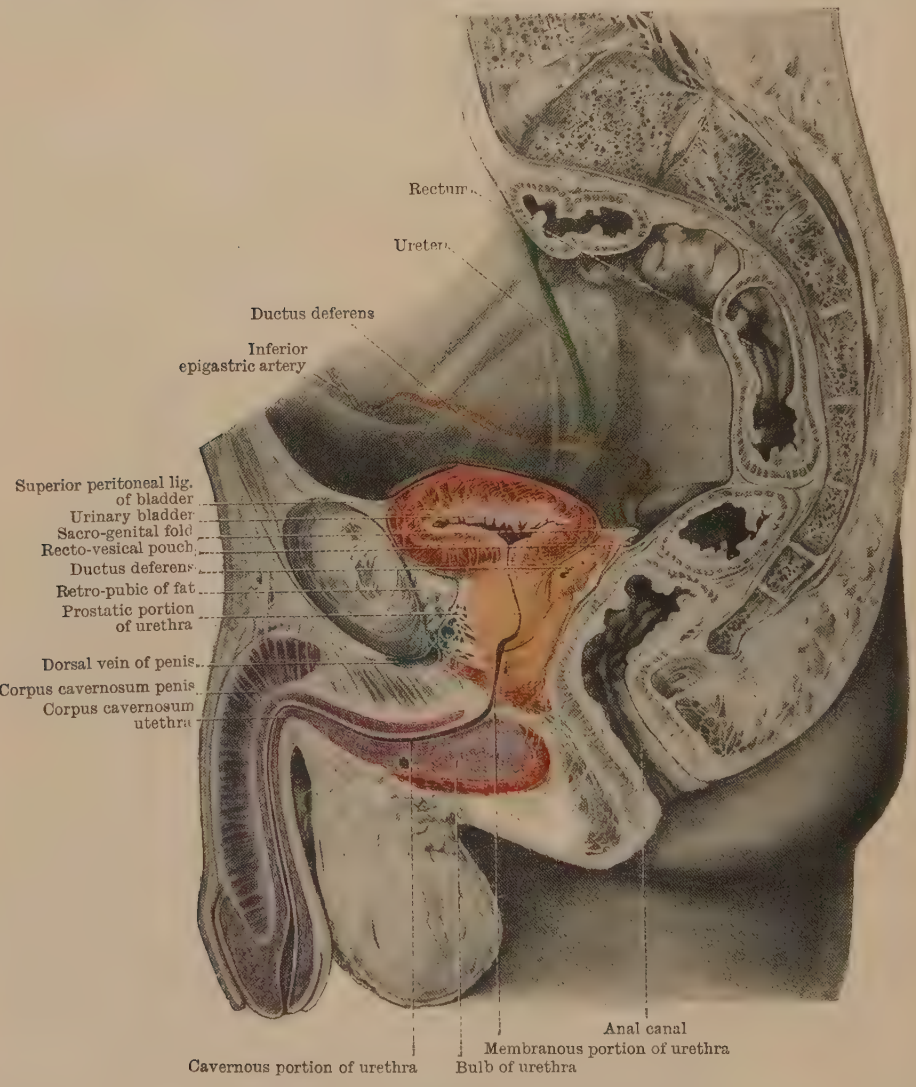

FIG. 998.—ADULT MALE PELVIS IN MEDIAN SECTION.

The urinary bladder is empty and firmly contracted. The urethra is opened up in its entire length.

and behind it, on each side of the median plane, lies the bulbo-urethral gland. The posterior part of the bulbus urethræ projects backwards and overlaps the posterior wall of the membranous part of the urethra to a considerable extent (Fig. 995).

The membranous portion of the urethra is the most firmly fixed and, excepting the external urethral orifice, least dilatable part of the passage.

A slight medial elevation, which is continuous above with the crista urethralis, projects into the canal from its posterior wall, and, becoming less marked as it is traced downwards, is often seen to divide into two faint ridges. When the canal is empty other longitudinal folds or ridges are usually to be seen on the mucous membrane, but these become obliterated when the passage is distended. The lumen of the empty tube, in transverse section, presents a stellate outline.

It is important to note that the end of the membranous portion of the urethra, where it is overlapped by the urethral bulb, lies in front of the uro-genital diaphragm. It is considerably wider than the upper part of this subdivision of the canal, and is very thin-walled. This is the part of the canal which is most liable to rupture (Figs. 995 and 999).

The third, or **cavernous portion**, of the urethra is much the longest of the three subdivisions. It begins at a point about half an inch in front of the posterior end of the bulbus urethræ, and ends at the external urethral orifice on the glans penis. Its proximal, or perineal, portion has a fixed position and direction, while

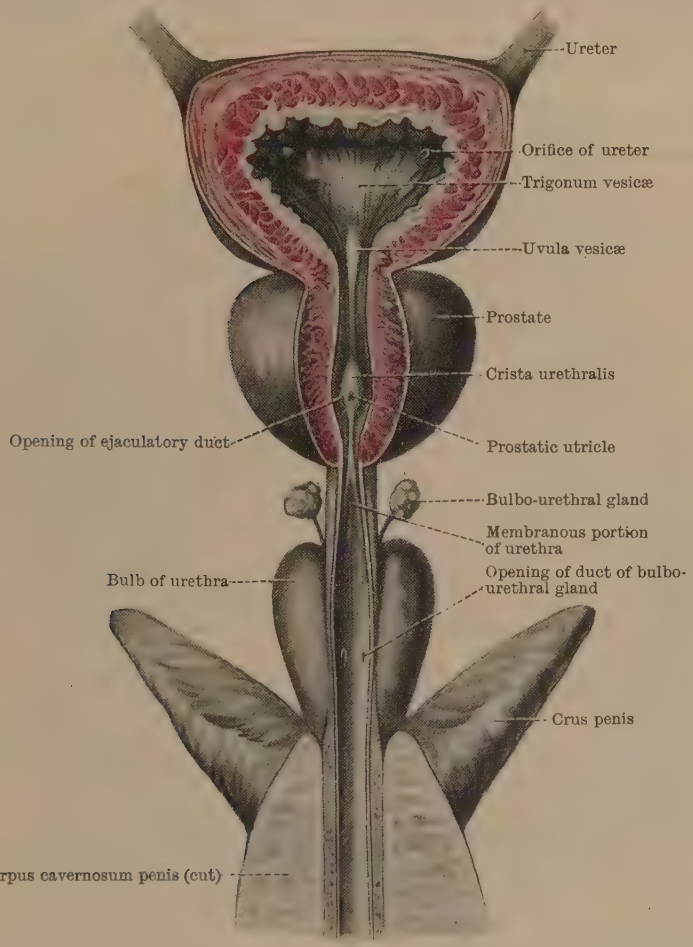

FIG. 999.—DISSECTION SHOWING THE TRIGONUM VESICÆ AND THE POSTERIOR WALL OR FLOOR OF THE URETHRA IN ITS PROSTATIC, MEMBRANOUS, AND THE PROXIMAL PART OF ITS CAVERNOUS SUBDIVISIONS.

The canal has been opened up by removing its anterior and upper wall.

its distal part varies with the position of the penis. The canal is about six inches in length, and is related throughout its whole extent to the erectile tissue of the corpus cavernosum urethræ and of the glans penis. Directed at first forwards through the bulbus urethræ, the canal turns downwards and forwards at the point where it comes to lie in front of the lower part of the symphysis pubis (Fig. 998). This bend in the direction of the canal, roughly speaking, corresponds to the place of attachment of the suspensory ligament to the dorsum of the penis. When the penis is drawn upwards towards the front of the abdomen, the direction of the terminal half of the canal is, of course, changed, and at the same time the whole length of this subdivision of the urethra becomes more uniformly curved.

The urethra passing obliquely downwards and forwards enters the bulb at a point nearly half an inch from its posterior extremity. Immediately after the canal has

pierced the inferior fascia of the uro-genital diaphragm its posterior aspect comes into relation with the erectile tissue of the bulb, but the anterior wall remains uncovered for a distance of about a quarter of an inch (Fig. 998). The wall of the urethra is here very thin, and the passage is more readily dilatable than in other parts. In this region the urethral wall may readily be torn through, if undue force is used, or if the handle of an instrument is depressed too soon when attempting to pass it into the narrower more fixed part of the canal. The urethra lies at first in the upper part of the erectile tissue, but as it passes forwards it sinks deeper, and comes to occupy the middle part of the corpus cavernosum urethræ (Fig. 998). In the glans, on the other hand, the erectile tissue lies on the dorsal and lateral aspects of the urethra. Like the other parts of the urethral passage, the cavernous portion is closed except during the passage of fluid, the closure being effected by the apposition of its dorsal and ventral walls except in the portion of the canal which lies in the glans penis, where the side walls of the canal come into contact. Thus the lumen of the first part of the canal, when empty, is represented in cross section by a transverse slit, and that of the terminal part by a vertical slit (Fig. 994). The cavernous part of the urethra does not present a uniform calibre throughout, but is narrower in its intermediate part, where it traverses the corpus cavernosum urethræ, than it is in those portions of its course which are surrounded by the bulb and the glans. The terminal dilated part of the passage is termed the **fossa navicularis urethræ**, and opens on the surface by the vertically placed slit-like **external urethral orifice**, which is the narrowest and least dilatable part of the whole urethral canal.

The ducts of the bulbo-urethral glands open by very minute apertures in the inferior wall of the proximal part of the cavernous portion of the urethra. Before opening into the canal, they lie for some distance immediately beneath its mucous membrane. A number of little pit-like recesses, called the **urethral lacunæ**, also open into the cavernous part of the urethra, and are so disposed that their openings lead for the most part obliquely into the canal in the direction of its external orifice.

In some cases a valve-like fold of the mucous membrane is found in the upper wall of the urethra in the region of the fossa navicularis. The free edge of this fold is directed towards the external urethral orifice, and may engage the point of a fine instrument introduced into the urethra.

Structure.—The mucous membrane of the urethra contains numerous elastic fibres and varies in thickness in different parts of the canal. In many positions it shows distinct longitudinal folds and also minute depressions or pits—the urethral lacunæ already mentioned. The lining epithelium is composed of many layers of cells, and is continuous through the internal urethral orifice with the epithelium of the bladder, which at first it closely resembles. In the region of the fossa navicularis the lining cells, which throughout the cavernous portion of the canal are of a columnar type, become flat and scaly.

Numerous minute glands—**urethral glands**—open into the urethra. These are most plentiful in the upper, or anterior, wall, but they also occur in smaller numbers in the floor and side walls. They are most numerous in the anterior half of the cavernous portion of the canal, and in the membranous subdivision of the urethra.

The larger glands are deeply placed beneath the mucous coat, and communicate with the urethra by long slender obliquely placed branched ducts. The smaller glands lie in the mucous coat and form flask-like depressions with very short ducts. The ducts of some of the glands open into the lacunæ, but many of the latter have no connexion with the urethral glands.

Frequently two or more elongated ducts belonging to some of the larger glands open into the urethra quite close to its termination. These are sometimes spoken of as *para-urethral ducts*, and may be traced backwards for some distance beneath the mucous membrane forming the roof of the urethra. Morphologically they do not correspond to the ducts which have in the female received the same name.

The muscular wall in the upper part of the urethra consists of smooth muscle fibres directed for the most part longitudinally, but some circularly arranged fibres are also present. It is probable that throughout the greater part of the cavernous urethra a muscular coat is not represented.

Round the beginning of the urethra there is an obliquely placed band of circularly arranged smooth muscle fibres, which is continued downwards and forwards from below the anterior part of the trigone of the bladder. The lower and anterior fibres of this band lie in the anterior wall of the upper part of the prostatic urethra. The band is sometimes spoken of as the sphincter vesicæ internus. At a lower level, in front of the prostatic urethra, is a band of striped muscular fibres which is continuous inferiorly with the inner circularly disposed part of the sphincter urethræ membranaceæ.

Like the latter it is probably to be regarded as a part of a primitive voluntary uro-genital sphincter muscle, such as is represented also in the female subject.

THE FEMALE REPRODUCTIVE ORGANS.

The reproductive glands in the female are a pair of **ovaries** placed one on each side of the cavity of the pelvis. In connexion with each ovary is an elongated passage or tube—the **uterine** or **Fallopian tube**—which leads to the uterus and opens into its cavity. There is no direct continuity between the ovary and the uterine tube, such as exists between the other glands of the body and their ducts, but the ova, when shed from the ovary, pass into the open end of the tube, and are thus conducted to the uterine cavity. The **uterus** is a hollow muscular organ which

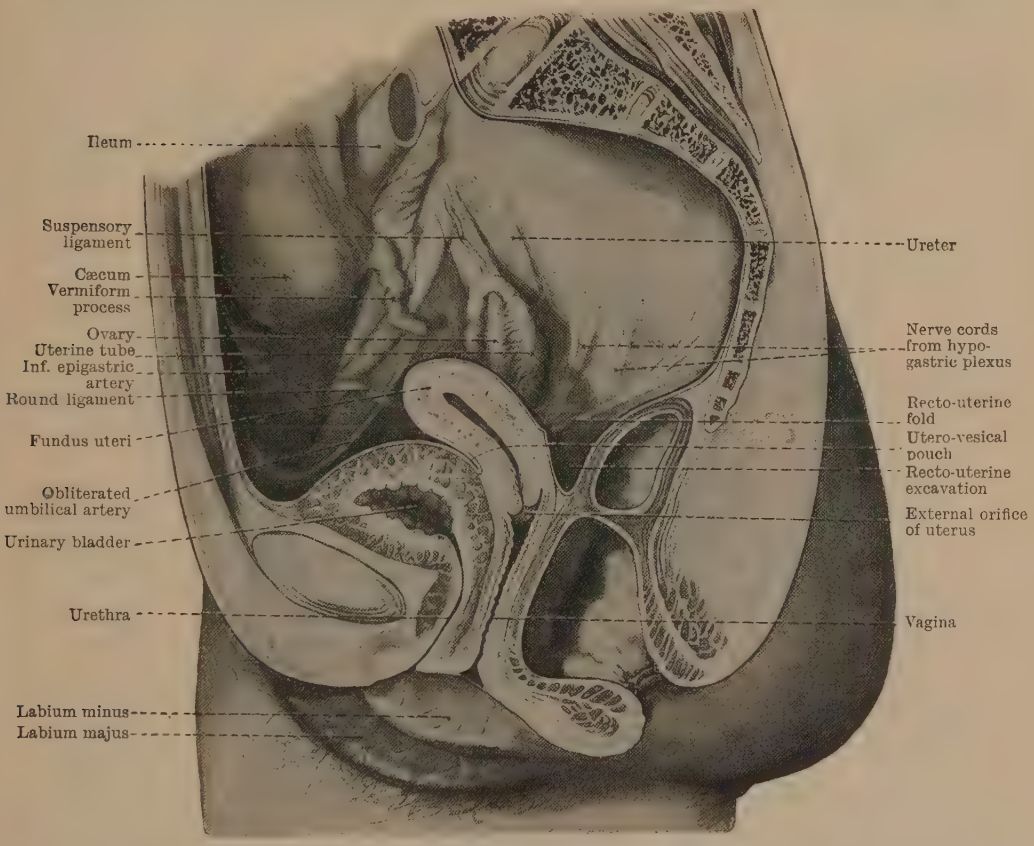

FIG. 1000.—MEDIAN SECTION THROUGH THE FEMALE PELVIS.
Drawn for the most part from a model made from a dissection by Professor Edward H. Taylor.

occupies a nearly median position in the pelvis. It is joined by the uterine tubes above, and communicates with the upper part of the vagina below. The ovum, having passed through the tube, reaches the cavity of the uterus, and in it, if fertilisation has taken place, the ovum undergoes its development into the embryo and fœtus. The **vagina** is the passage which leads from the uterus to the exterior, and has its external opening behind that of the urethra, within the **rima pudendi** or uro-genital cleft. In connexion with the uro-genital cleft are a number of structures which are included under the term *external genital organs*, and which represent in the female the various parts of the penis and scrotum in the male. These are the **labia majora** and the **mons pubis**, the **labia minora**, the **clitoris**, and the **bulbus vestibuli**. The **larger vestibular glands**, placed one on each side of the lower part of the vagina, are accessory organs of the female reproductive system, and represent the bulbo-urethral glands in the male.

OVARIUM.

The **ovary** is a solid body, flattened from side to side, and about the size and shape of a large almond. Its length is usually between one and one and a half inches, and the thickness from side to side between a quarter and half an inch. In the adult the ovary is placed against the side wall of the pelvic cavity, and is connected by peritoneal folds with the broad ligament of the uterus and with the side wall of the pelvis. The position occupied by the ovary within the pelvic cavity is fairly constant, although these peritoneal ligaments do not hold the organ firmly fixed in any definite place.

In the ovary we recognise two extremities — a *superior*, larger, and more rounded, and an *inferior*, somewhat pointed. The term **tubal extremity** is applied

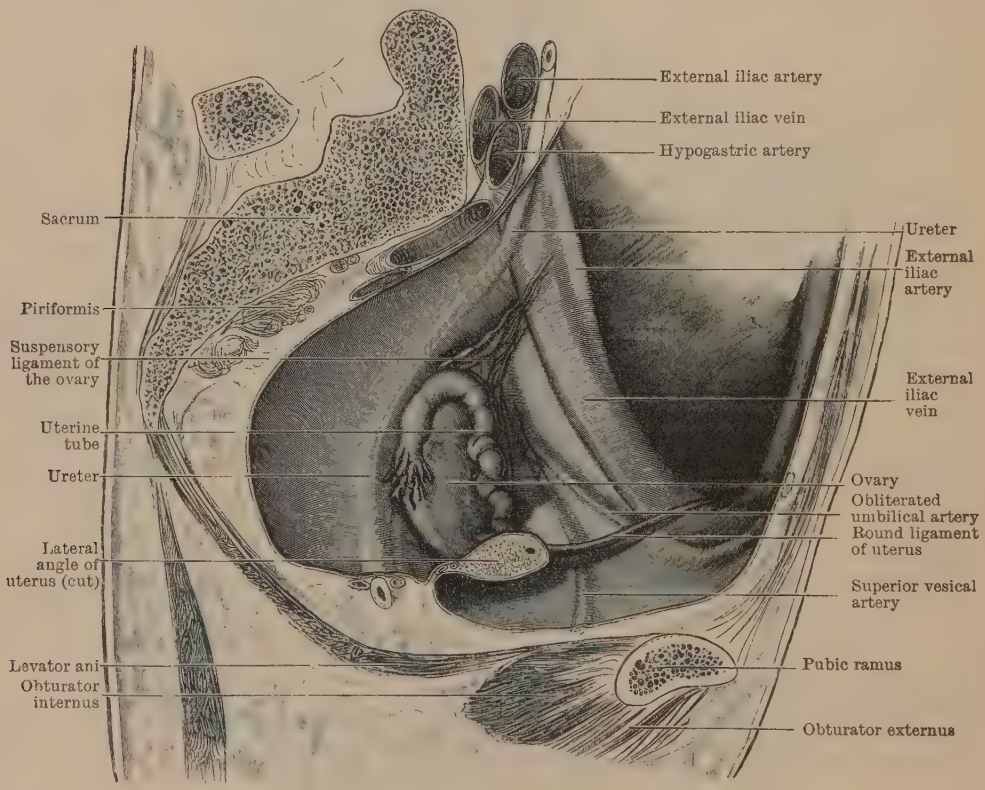

FIG. 1001.—SIDE WALL OF THE FEMALE PELVIS, showing the position of the ovary and its relation to the uterine tube. The pelvis has been cut in section parallel to, but at some distance from, the median plane.

to the superior end of the ovary, as it is most intimately connected with the uterine tube; the term **uterine extremity** is used with reference to the inferior extremity, since this part of the ovary is connected with the uterus by a fibrous cord, termed the **ligament of the ovary**. The flattened **surfaces** of the ovary are called **medial** and **lateral**, and the *borders* separating them the **mesovarian border**, and the **free border**. The free border is convex; while the mesovarian border, which is straighter and narrower, is connected by a very short peritoneal fold, the mesovarium, with the posterior layer of the broad ligament of the uterus. The vessels and nerves enter the ovary at this mesovarian border, which is therefore often termed the **hilum** of the ovary.

Position and Relations of the Ovary.—When the ovary occupies its most usual, or typical, position the long axis of the gland is vertical. Its lateral surface lies against the wall of the pelvis, and its medial surface looks into the

pelvic cavity. The peritoneum of the pelvic wall, where the ovary lies against it, is depressed to form a little fossa termed the *fossa ovarii*, within which the ovary is placed. Beneath the peritoneum forming the floor of this fossa are the obturator nerve and vessels. The tubal extremity of the ovary lies below the level of the external iliac vessels, and its uterine extremity is placed just above the level of the peritoneum covering the pelvic floor. The fossa ovarii, in which the ovary lies, extends as far forwards as the obliterated umbilical artery, and backwards as far as the ureter and uterine vessels. Thus the mesovarian border of the ovary lies just behind the line of the obliterated umbilical artery, and the free border is on a plane anterior to that of the ureter (Fig. 1001). The medial surface of the ovary is almost completely covered by the uterine tube, which, passing upwards on it near its mesovarian border, arches over the tubal extremity, and then turns downwards in relation to the free border and posterior part of the medial surface (Fig. 1001).

In some cases the ovary is found to lie behind, or more rarely in front of, the fossa described above, and its long axis may be oblique instead of vertical. The description given corresponds to the typical position of the organ in women who have not borne children. When the uterus is much inclined towards the right side of the body the left ovary has its long axis directed obliquely downwards and medially, the right gland remaining vertical.

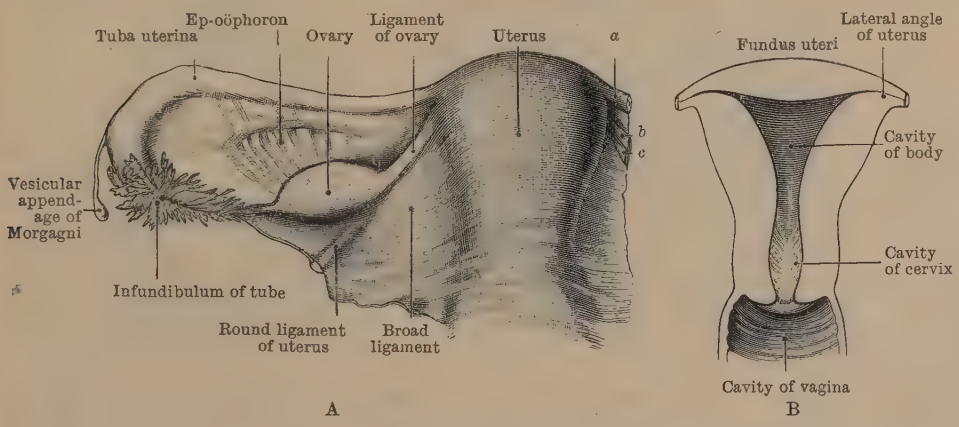

Fig. 1002.—A, The Posterior Aspect of the Uterus and Broad Ligament (the broad ligament has been spread out).

a, *b*, and *c*, the isthmus tubæ, the ligament of the ovary, and the round ligament of the right side cut short.

B, Diagrammatic Representation of the Uterine Cavity opened up from its Anterior Aspect.

Connexions of the Ovary.—When the ovary is in position a small somewhat triangular peritoneal fold passes upwards from its tubal extremity, and becomes lost in the peritoneum covering the external iliac vessels and the psoas major muscle (Fig. 1001). This fold has received the name of **suspensory ligament of the ovary**, and is a portion of the superior and lateral part of the broad ligament of the uterus, which here contains between its two layers the ovarian vessels and nerves as they pass down into the pelvis to reach the hilum of the ovary. The vessels and nerves entering the ovary along its mesovarian border are enclosed in a sheath of peritoneum derived from the posterior layer of the broad ligament. In this way the ovary is connected along the whole length of its anterior border by a very short mesentery, or **mesovarium**, to the posterior aspect of the broad ligament (Fig. 1002). The uterine extremity of the ovary is connected with the lateral angle of the uterus by a ligament called the **ligamentum ovarii proprium** or *ligament of the ovary*. This has the form of a rounded cord enclosed between the peritoneal folds of the broad ligament, and is attached to the uterus, behind and below the point of entrance of the uterine tube. It is composed chiefly of smooth muscle fibres continuous with those of the uterus. The tubal extremity of the ovary is directly connected with one of the largest of the fimbriæ surrounding the abdominal end of the uterine tube, which receives the name **ovarian fimbria** (Fig. 1002).

Descent of the Ovary.—Like the testes, the ovaries at first lie in the abdominal cavity, and only later assume a lower position. At birth the ovary lies partly in the abdominal, and partly in the pelvic cavity; soon, however, it takes up a position entirely within the pelvis minor. As in the male, a gubernaculum is present in the early stages of development. The ligament of the ovary represents the upper part of the gubernaculum which is developed within the plica testis inferior in the male, and the round ligament of the uterus represents the inferior part, which is formed within the plica inguinalis (see p. 1280). It is a rare abnormality for the ovary, instead of entering the pelvis, to take a course similar to that of the testis, and pass through the inguinal canal into the tissue of the labium majus.

Structure of the Ovary.—The ovary is for the most part composed of a connective tissue, called the **stroma of the ovary**, richly supplied by blood-vessels and nerves. The stroma contains very numerous spindle-shaped connective tissue fibres, and some elastic tissue. The surface of the ovary is covered by a layer of epithelium, which is composed of columnar cubical cells, and is continuous with the flat-celled epithelium of the peritoneum forming the mesovarium. The ovarian epithelium is a persistent portion of the germinal epithelium of the embryo which covers the genital ridges, and from which the oöcytes and other cells of the ovarian follicles are derived. The position in which it becomes continuous with the peritoneum can usually be distinguished as a fine white line near the hilum of the ovary. Shining through the epithelium of the fresh ovary (except in old age) are usually to be seen a variable number of small vesicles—the **vesicular ovarian follicles**, in which the egg cells or oöcytes are contained. The number of follicles visible, and also the size which each follicle reaches before it ruptures and sheds its contents, is by no

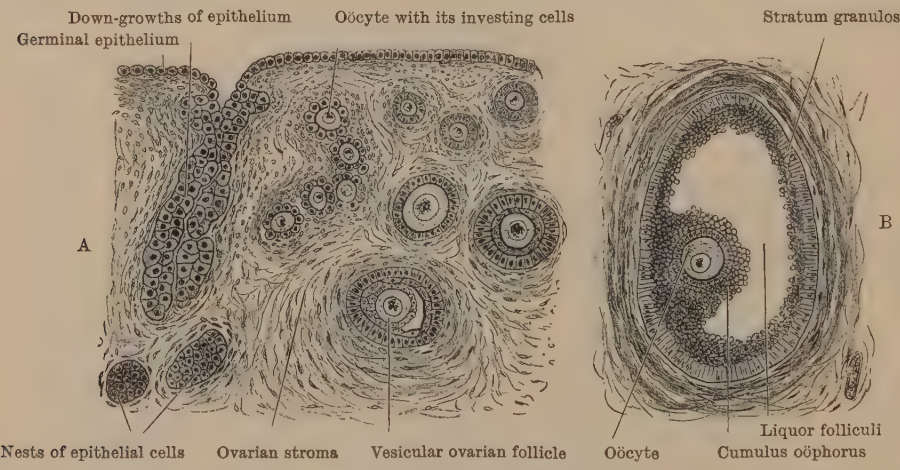

Fig. 1003.—A. Diagrammatic Representation of the Manner in which the Vesicular Follicles arise during the Development of the Ovary. B. Diagram illustrating the Structure of a Ripe or Vesicular Ovarian Follicle.

means constant. When a follicle ruptures and discharges the oöcyte its walls at first collapse, but later the cavity becomes filled with extravasated blood and cellular tissue of a yellowish colour. The resulting structure, called a **corpus luteum**, slowly degenerates unless impregnation has taken place, in which case it develops and becomes larger during pregnancy. As it atrophies the cells of the corpus luteum disappear, and the structure, losing its yellow colour, receives the name of **corpus albicans**. After a time the corpus albicans completely disappears. Owing to the periodic rupture of the ovarian follicles, the surface of the ovary, which is at first smooth and even, becomes in old age dimpled and puckered.

A section through the ovary, especially in young children, presents in its superficial part a somewhat granular appearance, which is due to the presence of large numbers of small follicles, or collections of epithelial cells, embedded in the connective tissue near the surface of the ovary. The larger follicles lie deeper in the stroma, but when they become fully developed they pass towards the surface, where the ripe follicles are often seen slightly projecting and ready to burst. In the deepest part of the ovary the blood-vessels are most numerous, and here also some smooth muscle fibres are found.

The oöcytes and the other cells that compose the ovarian follicles are derived originally from the germinal epithelium which covers the developing ovary in the embryo. The epithelium, at first simple, grows down into the underlying tissue in the form of branching tube-like processes, or "egg tubes." This takes place during fœtal development, and the branching cellular processes so formed become broken up, within the stroma, into little nests or clumps of cells, each of which becomes a follicle. From the beginning some cells of the egg tubes are larger than the others; these become the future ova, while the cells round them become the investing cells of the follicle. The investing cells, at first flattened, form a single layer round each oöcyte. Later, becoming columnar, as the follicle increases in size and sinks more deeply in the stroma, these cells divide in such a manner that the oöcyte becomes surrounded by a double layer of cells. Fluid—**liquor folliculi**—accumulates between the two cellular layers, except at one place where

the inner cells surrounding the ovum remain attached to the outer layer or **stratum granulosum**. To the inner cellular mass enclosing the oöcyte, the term **cumulus oöphorus** is applied (Fig. 1003). The ripe follicle contains a relatively large amount of fluid, and the surrounding stroma becomes differentiated to form a capsule or **theca folliculi**. This capsule is composed of an inner more *vascular layer*, the **tunica interna**, and an outer more *fibrous layer*, the **tunica externa**. There is reason to believe that in the human subject the formation of ova and follicles ceases before birth, and that the appearances which have led to the belief that they may originate during the first years of extra-uterine life have been due to pathological conditions. In the young child there are numerous small follicles in the superficial parts of the ovary, but in old age none are found in this situation.

The appearance and structure of the ripe ova are described on pp. 17-19.

Vessels and Nerves of the Ovary.—The **ovarian arteries**, corresponding to the testicular arteries of the male, are a pair of long slender vessels which spring from the anterior aspect of the aorta, below the level of origin of the renal vessels. Each gains the pelvis minor in the fold of peritoneum forming the suspensory ligament of the ovary, and enters the ovary at its mesovarian border. The ovarian artery anastomoses freely, near the hilum, with other vessels, derived from the **uterine arteries**. The blood is returned by a series of communicating veins, similar to the **plexus pampiniformis** in the male.

The **nerves** of the ovary are derived chiefly from a plexus which accompanies the ovarian artery, and which is continuous above with the renal plexus. Other fibres are derived from the inferior part of the aortic plexus, and join the plexus on the ovarian artery. The afferent impulses from the ovary reach the central nervous system through the posterior root fibres of the tenth thoracic nerve.

The **lymph-vessels** of the ovary join with those from the upper part of the uterus, and end in the lumbar lymph-glands.

TUBÆ UTERINÆ.

The **uterine** or **Fallopian tubes** are a pair of ducts or passages which convey the oöcytes, discharged from the follicles of the ovaries, to the cavity of the uterus. Each tube is about four and a quarter inches in length, and opens at one end into the pelvic cavity near the ovary, and at the other end by a smaller opening into the lateral part of the uterine cavity. The tube is enclosed in a fold of peritoneum called the **mesosalpinx**, which is a portion of the broad ligament of the uterus.

The opening of the tube into the pelvic cavity—the **abdominal ostium**—is of small size, being only about 2 mm. in diameter when its walls are relaxed, and much narrower when the muscular coat of the tube is contracted. This opening is placed at the bottom of a funnel-like expansion of the tube called the **infundibulum**, the margins of which are produced into a number of irregular processes or **fimbriæ**. The presence of these fimbriæ, many of which are branched or fringed, has given the name *fimbriated extremity* to this end of the uterine tube. The surface of the fimbriæ which looks into the cavity of the infundibulum is covered by a mucous membrane continuous with that lining the tube, while the outer surface is clothed by peritoneum. The mucous surfaces of the larger fimbriæ present ridges and grooves which are continued into the folds and furrows of the mucous coat of the tube. One of the fimbriæ, usually much larger than the rest, is connected either directly or indirectly with the tubal extremity of the ovary, and to it the name **ovarian fimbria** is applied. The part of the tube continuous with the infundibulum, and into which the ostium abdominale leads, is called the **ampulla**. This, the widest and longest portion of the uterine tube, is usually tortuous and of varying diameter, being in some places slightly constricted, and in others distended. The wide, thin-walled ampulla ends in the narrower, thicker-walled, and much shorter **isthmus** of the tube which joins the lateral angle of the uterus. The last portion of the canal, or *pars uterina*, is embedded in the substance of the uterine wall, which it traverses to reach the cavity of the uterus (Fig. 1004). The opening into the uterus, or **ostium uterinum**, is smaller than the abdominal ostium, being about 1 mm. in diameter. The lumen of the canal gradually increases in width as it is traced outwards from the uterus towards the ovary.

Course of the Uterine Tube.—Traced from the lateral angle of the uterus the uterine tube is directed at first horizontally in a lateral direction towards the uterine extremity of the ovary. It then passes upwards in relation to the medial side of the mesovarian border of the ovary, until it reaches the tubal extremity of the gland. Next arching backwards, it descends along the posterior or free border of the ovary and rests against its medial surface (Fig. 1001). As the uterine tube

describes this loop it often covers almost the entire medial surface of the ovary. The fimbriated end of the tube is applied against the free border and inferior part of the medial surface of the ovary, and from it the ovarian fimbria passes upwards to gain attachment to the tubal extremity of the gland.

The fimbriated end of the uterine tube lies in the abdominal cavity until the ovary in its descent has entered the pelvis.

Structure of the Uterine Tubes.—The wall of each tube, which is surrounded by a **serous coat**, derived from the peritoneum, is composed of a number of concentric layers. Immediately beneath the peritoneum is a thin layer of loose connective tissue, the **tunica adventitia**, in which lie many vessels and nerves. Beneath this is the **muscular coat** composed of two strata of smooth muscle fibres—a more superficial thin stratum of longitudinally arranged fibres, and a deeper thicker layer, the fibres of which are circularly disposed. Deeper is a *submucous layer*, and then the lining membrane or **mucous coat**. In the part of the tube near the uterus the muscular layer is thicker than towards the other end, and in the isthmus it forms the chief part of the wall. The mucous membrane, on the contrary, is thickest towards the fimbriated end, and here it forms the chief part of the tube wall. The stratum of circular muscle fibres is especially well developed near the uterus. The mucous membrane is thrown into numerous longitudinal folds, or **plicæ**, which in the ampulla are exceedingly complex, the larger ones being beset on the surface by smaller folds. In transverse sections of this part of the tube the folds of the mucous membrane look like large branching processes projecting into, and almost completely filling up, the lumen of the tube. The mucous membrane is covered by a ciliated epithelium, the cilia of which tend to drive the fluid contents of the tube towards the uterus. The epithelium is continuous with that of the uterus, and at the fimbriated end joins the peritoneum.

Vessels and Nerves of the Uterine Tube.—The uterine tube receives its chief **blood supply** from a tubal branch of the uterine artery, but it also receives small branches derived from the ovarian artery. The veins of the tube pour their blood partly into the uterine and partly into the ovarian veins. The **lymph-vessels** join the lumbar group of lymph-glands. The **nerves** are derived from the plexus that supplies the ovary, and also from the plexus in connexion with the uterus. The afferent fibres are believed to belong to the eleventh and twelfth thoracic and the first lumbar nerves.

EP-OÖPHORON AND PAR-OÖPHORON.

The ep-oöphoron and the par-oöphoron are two vestigial structures found between the layers of the broad ligament.

The **ep-oöphoron** or **parovarium** lies in the mesosalpinx between the uterine tube and the ovary. In the adult it consists of a number of small rudimentary blind tubules lined by an epithelium. One of these tubules—the **longitudinal duct** (of Gärtner)—lies close to, and runs nearly parallel with, the uterine tube. It is joined by a number of **transverse ductules** which enter it at right angles, from the neighbourhood of the ovary. The longitudinal duct is a persistent portion of the Wolffian duct, and represents the canal of the epididymis in the male, while the tubules which join it are derived from the mesonephros and represent the efferent ductules of the testis (and probably also the ductuli aberrantes of the duct of the epididymis). The ep-oöphoron is best seen when the part of the broad ligament in which it lies is held up to the light.

One or more small pedunculated cystic structures, called **vesicular appendices**, are often seen near the infundibulum of the uterine tube. These are supposed to represent portions of the cephalic end of the Wolffian duct.

The **par-oöphoron** is a collection of very minute tubules also enclosed by the layers of the mesosalpinx, but lying nearer the uterus than the ep-oöphoron. These represent the paradidymis in the male, and are derived from the part of the mesonephros which lies nearer the caudal end of the body of the embryo. Though sometimes visible in the child at birth, the par-oöphoron in the adult can only be recognised by microscopic examination.

UTERUS.

The **uterus**, or womb, is a hollow, thick-walled, muscular organ placed within the pelvis between the bladder in front and the rectum behind. The ova discharged from the ovary enter the uterus through the uterine tubes, and, if fertilisation has taken place, undergo their development within it. In form the uterus is somewhat pear-shaped, the wide upper end of the organ projecting freely upwards and forwards into the pelvic cavity, while the lower more constricted part is connected

with the vagina. The usual length of the adult uterus (when non-pregnant) is three inches, its greatest breadth is nearly two inches, and its maximum thickness is about one inch. In the description of the uterus we distinguish between an upper larger portion, somewhat flattened from before backwards, forming the fundus and body, and a lower more cylindrical part called the cervix (Fig. 1004).

The part of the uterus that lies above the level of a line joining the points of entrance of the uterine tubes is called the **fundus uteri**. The fundus is convex from before backwards and from side to side, its anterior and posterior aspects being directly continuous with the anterior and posterior surfaces of the body of the organ.

The **corpus uteri**, when seen from in front or from behind, has a somewhat triangular outline, and lies below the fundus, with which it is continuous. The base of the triangle is directed upwards and is formed by a line joining the lateral angles of the uterus, or points of entrance of the uterine tubes; and the sides of the triangle correspond to the lateral borders of the uterus, which extend on each side from the lateral angle to the cervix. The **lateral borders** separate the **anterior** or **vesical surface** from the **posterior** or **intestinal surface** of the body. Both these surfaces are convex, but the intestinal is much the more rounded. The vesical surface rests against the upper aspect of the bladder, from which usually it is separated by the layers of peritoneum forming the utero-vesical pouch. The intestinal surface forms the chief part of the anterior wall of the deep recess situated between the uterus and rectum, and is usually in contact with some part of the small intestine or the pelvic colon. The broad ligament passes laterally on each side of the uterus from the lateral border of the organ.

The **cervix uteri** is cylindrical, and at its commencement it is sometimes marked off from the body by a slight constriction. Its length is about one inch, and its inferior end, tapering somewhat, enters the upper part of the vagina. The cervix is attached to the margin of the opening in the vaginal wall, through which it passes, and in this way a **supravaginal portion** is marked off from a **vaginal portion** of the cervix. In the vaginal portion of the cervix there is an opening, the **external orifice**, through which the cavity of the uterus communicates with that of the vagina. In a uterus which has not been pregnant this opening is nearly circular, but in women who have borne children it is usually a transverse slit with a somewhat irregular outline. In front of, and behind, this opening the cervix forms two lips, an anterior and a posterior. The *anterior lip* is thicker, and slightly more rounded; it is placed upon a lower level than the *posterior lip*, which is slightly longer and thinner. The cervix enters the vagina through the upper part of its anterior wall in such a manner that the external orifice of the uterus is directed backwards and downwards against the upper part of the posterior vaginal wall (Fig. 1000).

Cavum Uteri.—In comparison with the size of the organ, the **cavity of the uterus** is of small size owing to the great thickness of the uterine wall. In the body, the cavity is merely a narrow chink between the anterior and posterior walls, which are almost in contact (Fig. 1000). When, however, the uterus is opened from above downwards in frontal section of the organ, the cavity of the body has a triangular outline (Fig. 1004). The base of the triangle is directed upwards, and corresponds to a line drawn between the openings of the uterine tubes, while the apex is directed downwards towards the cervix. The sides of the triangle are convex inwards towards the cavity. The cavity of the body becomes continuous with that of the cervix by an opening called the **internal orifice** of the uterus, which is a little smaller and more circular than the external orifice of the uterus. The cavity of the cervix, or **cervical canal**, extends from the internal orifice of the uterus, where it joins the cavity of the body, to the external orifice, where it opens into the vagina. It is a somewhat spindle-shaped passage, which is narrower above and below than in its middle part. Sections show also that its antero-posterior diameter is shorter than its transverse, owing to an approximation of its anterior and posterior walls. In the body of the uterus the walls of the cavity are smooth and even, but in the cervical canal the mucous membrane forms a remarkable series of folds, called the **plicæ palmatæ**. These consist of an anterior and a posterior longitudinally directed fold or ridge, from which a large

number of secondary folds, or rugæ, branch off obliquely upwards and laterally (Fig. 1004, B).

Connexions of the Uterus and its Relations to the Peritoneum.—In addition to the uterine tubes at its upper lateral angles, and the vagina below, the uterus possesses other important connexions. Some of these are simply peritoneal folds passing from the uterus to neighbouring structures; others contain fibrous connective tissue, or smooth muscle fibres.

The peritoneum covering the fundus of the uterus is continued down over the vesical surface as far as the junction of the body and cervix, where it leaves the uterus to be reflected on to the bladder, forming the *utero-vesical fold*, or "anterior ligament of the uterus." The peritoneal recess between the bladder and the uterus is called the **vesico-uterine excavation**, or *utero-vesical pouch*. Below the level of this pouch the anterior aspect of the cervix is connected by loose tissue with the wall of the bladder. Posteriorly the peritoneum covers the whole of the uterus, except the small portion of the cervix which projects into the upper part of the vagina. The peritoneum covering the intestinal surface of the uterus is continued

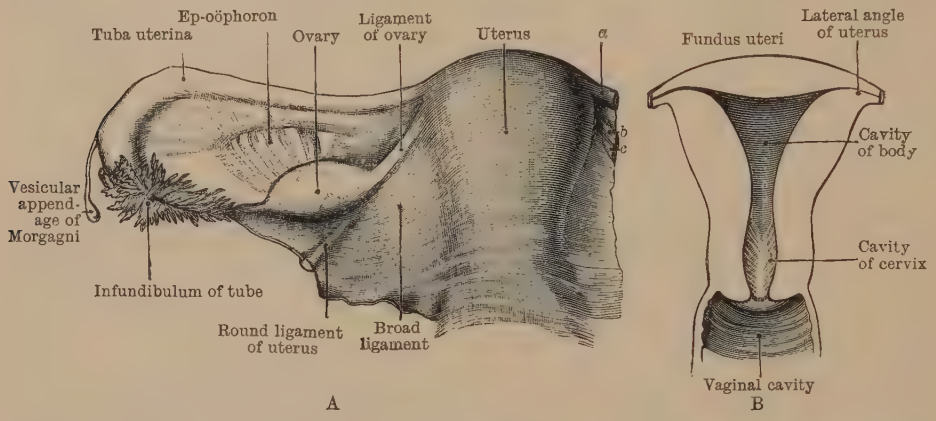

FIG. 1004.—A. THE POSTERIOR ASPECT OF THE UTERUS AND BROAD LIGAMENT (the broad ligament has been spread out).

B. DIAGRAMMATIC REPRESENTATION OF THE UTERINE CAVITY OPENED UP FROM ITS ANTERIOR ASPECT.

to such a depth that it invests a small portion of the upper part of the posterior wall of the vagina before it is reflected on to the rectum, to form the *recto-vaginal fold* or "posterior ligament of the uterus" (Fig. 1005). The deep pouch between the uterus and vagina in front and the rectum behind is called the **recto-uterine excavation**, or *pouch of Douglas*, and its entrance is bounded on each side by a crescentic peritoneal fold, which passes from the posterior surface of the cervix uteri to the posterior wall of the pelvis, and ends near the side of the rectum. These are known as the sacro-genital folds, or **recto-uterine folds** of Douglas, and each contains between its layers a considerable amount of fibrous and smooth muscular tissue. A few of these fibres, which are continuous with the uterine wall, pass backwards to reach the rectum and constitute the **recto-uterine muscle**; others are said to gain an attachment to the front of the sacrum, and form a *utero-sacral ligament*. In many cases the recto-uterine folds become continuous with one another across the median plane behind the cervix uteri, and form, in this position, a transverse ridge termed the *torus uterinus*. The recto-uterine pouch of the female represents the recto-vesical or recto-genital pouch of the male, and the folds which bound it on each side, namely, the recto-uterine folds, correspond to the sacro-genital folds (sometimes called posterior peritoneal ligaments of the bladder) in the male sex (p. 1268).

The peritoneum of the vesical and intestinal surfaces, leaving the uterus along each lateral border to reach the side wall of the pelvis, forms the broad ligament of the uterus.

LIGAMENTUM LATUM UTERI.

The **broad ligament of the uterus** is a wide peritoneal fold which passes from the lateral border of the uterus to the pelvic wall, and contains between its layers several important structures (Fig. 1004). The plane of the medial part of the ligament is determined by the position of the uterus. When the uterus is placed normally, the ligament has an anterior surface which looks downwards as well as forwards, and a posterior one which looks upwards and backwards. Near its attachment to the pelvis the ligament is placed more vertically. The free edge of the ligament contains the uterine tube, and follows the course pursued by that structure. Thus, in the undisturbed condition of parts, it at first passes laterally towards the uterine extremity of the ovary, and then ascends to arch over the tubal pole of the ovary on its medial side. Owing to the course pursued by the uterine tube round the ovary, the broad ligament forms a kind of curtain over the gland, and the ovary lies in a little pocket formed by the broad ligament, to which the name of **bursa ovarica** is applied (Figs. 1000 and 1001). This bursa ovarica is not to be confused with the *fossa ovarii*, or depression on the side wall of the pelvis, against which the ovary is usually placed (p. 1295).

The various structures in connexion with the broad ligament are most easily demonstrated when the ligament is spread out as flat as possible.

The ovary is connected with the posterior layer of the broad ligament by a very short mesentery, called the **mesovarium**, which, passing to the hilum, encloses the ovarian vessels and nerves as they reach the ovary.

The part of the broad ligament which slings the uterine tube is called the **mesosalpinx**. When the ligament is spread out, the mesosalpinx has the form of a narrow triangle, the apex of which is at the lateral angle of the uterus, while the upper side is formed by the uterine tube, and the lower one by the ligament of the ovary and the ovary itself. The narrow base of the triangle is directed laterally. In the normal position of the parts the mesosalpinx is folded round the ovary in the manner described above to form the bursa ovarica. Between the layers of this part of the broad ligament are situated the ep-oöphoron and the par-oöphoron (Fig. 1004).

The part of the broad ligament below the level of the mesosalpinx is termed the **mesometrium**. It contains, especially in its lower part, a considerable amount of connective tissue and unstriped muscle fibres. The ureter and the uterine vessels lie in the lowest part of the broad ligament where it joins the pelvic floor. The fibrous and smooth muscle tissue which occupy the interval between the layers of the lower part of the broad ligament, immediately below the uterine artery, form what is known as the *lateral cervical ligament* of the uterus. This ligament is continuous with the dense tissue surrounding the branches of the hypogastric artery, and in vertical antero-posterior section has a triangular outline near its attachment to the cervex uteri.

The highest part of the attached lateral portion of the broad ligament forms the **suspensory ligament of the ovary**, and contains between its layers the ovarian vessels and nerves as they enter or leave the pelvis.

The **ligament of the ovary** is a rounded fibrous cord, of about one inch in length, which is attached by its lateral end to the uterine pole of the ovary, and by its medial end to the lateral angle of the uterus immediately below and behind the entrance of the uterine tube. This ligament, which is largely composed of unstriped muscle fibres continuous with those of the uterus, is enclosed in a slight fold derived from the posterior layer of the broad ligament.

The ligament of the ovary represents the upper portion of the gubernaculum which appears in the embryo.

The **round ligament of the uterus** is a narrow flat band attached to the uterus just in front of, and a little below, the opening of the uterine tube. Near the uterus it contains numerous smooth muscle fibres, which are continuous with those of the uterine wall; more laterally it is composed chiefly of fibrous connective

tissue. Lying in the anterior part of the broad ligament, it reaches the wall of the pelvis minor, and is then directed forwards and slightly upwards to cross the obliterated umbilical artery and the pelvic brim. After it has reached the pelvic wall its course is comparable to that of the ductus deferens in the male, and, like the latter, it leaves the abdomen to traverse the inguinal canal (Figs. 1000 and 1001). It finally ends in the subcutaneous tissue and skin of the labium majus. Its terminal part is composed of connective tissue only.

The round ligament of the uterus represents the lower portion of the gubernaculum testis which appears in the male embryo (see p. 1280).

In some cases a minute diverticulum of the peritoneal cavity can be traced accompanying the round ligament through the abdominal wall. This is a vestige of the **processus vaginalis** of the peritoneum which is formed in the embryo in both sexes. The term "canal of Nuck" is sometimes applied to it when it is found in the adult female.

Position and Relations of the Uterus.—The position occupied by the uterus in the pelvis is not always the same, but varies with the conditions of the neighbouring organs. The lower cervical part is, however, much more firmly fixed in place than the body and fundus, which possess a considerable amount of mobility. Usually the level of the external orifice of the uterus will be found to correspond to that of a horizontal plane passing through the upper margin of the symphysis pubis. The uterus rarely lies exactly in the median plane of the body, but bends a little to one or other side, most frequently towards the right.

The vesical surface of the uterus rests against the bladder, and follows the rising or falling of its superior wall as that organ becomes filled or emptied. When the bladder is empty the long axis of the uterus points forwards and upwards, and the organ is said to be in an *anteverted* position. Also, the long axis of the uterus is bent on itself where the body joins the cervix, and so the organ is said to be *anteflexed*. The anteflexion is due to the fact that the more rigid cervix is fixed, while the movable upper part of the uterus sinks forwards, following the bladder wall. With the empty condition of the bladder the angle formed between the long axis of the uterus and that of the vagina is about a right angle. When the bladder becomes filled, the anteversion and anteflexion of the uterus become less marked, owing to the body and fundus being pushed backwards. Finally, if the rectum is empty and the bladder very much distended, the uterus is pushed so much backwards that the long axis of the organ may nearly correspond to that of the vagina. The uterus is then said to be *retroverted*. Superiorly a part of the peritoneal cavity intervenes between the vesical surface of the uterus and the bladder, but lower down the two organs are separated merely by a small quantity of connective tissue.

The intestinal surface of the uterus looks into the recto-uterine excavation, and is usually, like the fundus, in relation to some loops of the small intestine or the pelvic colon. Laterally the uterus is related to the broad ligament. The terminal portion of the ureter passes downwards, medially, and a little forwards across the lateral aspect of the cervix, but is separated from it by an interval of about three-quarters of an inch. The lowest part of the cervix is, as we have seen, enclosed within the cavity of the vagina.

On each side of the cervix uteri and upper part of the vagina there is an interval in which lie numerous large vessels. These are surrounded by bundles of smooth muscle fibres and by loose fatty tissue, which is continued upwards for a considerable distance between the layers of the broad ligament. This loose tissue, which is of surgical importance, has received the name **parametrium**.

Supports of the Uterus.—It is probable that during life the uterus is maintained in its normal anteverted and anteflexed position by the fixation of the cervix at the anterior vaginal wall and by the pull of the numerous strands of smooth muscle fibre which form the utero-sacral, the lateral cervical, and the round ligaments. Inferiorly the uterus is supported by the levator ani muscle forming the pelvic floor. The pressure and counter-pressure exerted by the bladder, colon, and rectum also influence the position of the uterus.

Structure of the Uterus.—The thick uterine wall is composed of three chief layers, which are termed respectively the serous, the muscular, and the mucous coats.

The **serous coat**, or *perimetrium*, is derived from the peritoneum. Over the fundus and body of the uterus it is very firmly adherent to the deeper layers, and cannot be easily peeled off without

tearing either it or the underlying muscular tissue. Near the lateral borders of the uterus the peritoneum is less firmly attached, and over the posterior aspect of the cervix it may readily be stripped off without injury to the underlying structures.

The **muscular coat** is composed of unstriped fibres, and forms the chief part of the uterine wall. Inferiorly the muscular coat of the uterus becomes continuous with that of the vagina. The more superficial layer of the muscular coat sends prolongations into the recto-uterine folds, into the round and broad ligaments of the uterus, and into the ovarian ligaments. Other fibres join the walls of the uterine tubes. The main branches of the blood-vessels and nerves of the uterus lie among the muscle fibres. In the deeper layers of the muscular coat a considerable amount of connective tissue and some elastic fibres are to be found. The muscular coat of the cervix contains more connective and elastic tissue than that of the body, and hence the greater firmness and rigidity of the cervical part of the uterus.

The deeper and thicker part of the muscular tissue of the uterus is considered by some anatomists to represent a muscularis mucosæ, and is therefore described as part of the mucous coat. The deep and superficial portions of the muscular coat are, however, quite continuous, and there is no representative of a submucous vascular layer of tissue such as in the alimentary canal separates the muscular coat from the muscularis mucosæ. In the uterus the blood-vessels lie in the muscular coat.

The **mucous coat** in the body of the uterus is smooth and soft, and covered with columnar ciliated epithelium. Simple tubular glands, also lined with a ciliated epithelium, are present in the mucous membrane, and penetrate in their deeper parts into the muscular coat. In the cervix of the uterus the mucous coat is firmer and more fibrous than in the body, and its surface is not smooth, but presents a number of peculiarly disposed ridges which have been already described (p. 1299). Like the mucous membrane of the body of the uterus, that of the cervix is covered with a ciliated epithelium which passes into squamous epithelium just inside the external orifice of the uterus. In addition to unbranched tubular glands, numerous somewhat branched glands are found in the cervix uteri. Both kinds of glands are lined by ciliated epithelium. In many cases little clear retention cysts, "ovules of Naboth," are to be seen in the cervical mucous membrane. These arise as a result of obstruction at the mouths of the glands.

Differences in the Uterus at Different Ages.—At birth the cervix uteri is relatively larger than in the adult organ, and its cavity is not distinctly marked off from that of the body by an internal orifice. At this time also the plicæ palmatæ extend throughout the whole length of the uterus. The organ grows slowly until just before puberty, when its growth is rapid for a time. As the body of the uterus increases in size the mucous membrane becomes smooth and the plicæ palmatæ become restricted to the cervix. In women who have borne children the cavity remains permanently somewhat wider and larger than in cases where the uterus has never been pregnant.

In old age the uterine wall becomes harder and has a paler colour than it possesses in the young subject.

Variations.—In rare cases the uterus may be divided by a septum into two distinct cavities, or its lateral angles may be produced into straight or curved processes, called "horns" or cornua. The latter abnormality recalls the appearance of the bicornuate uteri of some animals. Both the above conditions arise from an arrest in the fusion of the two separate tubes—the Müllerian ducts—which normally unite in the embryo to form the uterus.

Periodic Changes in the Uterine Wall.—At each menstrual period a remarkable series of changes occurs which results in a periodic shedding of the superficial parts of the uterine mucous membrane. For a few days before menstruation begins, the mucous membrane gradually thickens and becomes more vascular, while at the same time its surface becomes uneven. Soon the superficial parts of the mucous membrane disintegrate and hæmorrhage takes place from the small superficial blood-vessels. In this way a hæmorrhagic discharge is caused, and the superficial parts of the uterine mucous membrane are shed at each period. When menstruation is over the mucous membrane is rapidly regenerated.

Pregnant Uterus.—The pregnant uterus increases rapidly in size and weight, so that from being three inches in length and one ounce in weight, it becomes by the eighth month of pregnancy about seven or eight inches in length and sometimes as much as two pounds in weight. In shape the uterus is now oval or rounded, with a thick wall composed chiefly of muscle fibres arranged in distinct layers. The rounded fundus is very prominent. The round ligaments are stronger and better marked, and the layers of the broad ligament become separated in their medial parts by the growth of the uterus between them. The blood-vessels, especially the arteries, are very large and tortuous. The changes which occur in the mucous membrane of the pregnant uterus are intimately connected with the manner in which the developing fœtus receives its nutrition, and have been noticed on p. 61 *et seq.*

The uterus receives its **arterial supply** mainly from the uterine arteries, which are branches of the hypogastric arteries, and also from the ovarian arteries, branches of the aorta. The vessels derived from these two sources communicate freely with one another. Each uterine artery, reaching the side of the lower part of the uterus, divides into a large branch which passes upwards to supply the body and fundus, and a much smaller branch which passes downwards to supply the cervix. The vessels distributed to the body and fundus have an exceedingly tortuous course. The branches of the uterine artery, having entered the muscular coat, break up within its deeper layers into smaller twigs which supply the muscular tissue and the mucous coat. The small uterine branch from the ovarian artery reaches the uterus in the region of the lateral angle. During pregnancy the arteries become enormously enlarged.

The thin-walled **veins** form a plexus which pours its blood into the tributaries of the hypogastric vein.

The **nerves** of the uterus are derived chiefly from a plexus placed in the neighbourhood of the cervix uteri, to which the term plexus utero-vaginalis or "cervical ganglion" is applied. Superiorly this plexus is continuous with the hypogastric plexus, but it also receives fibres from the second, third, and fourth sacral nerves.

Clinical observations indicate that afferent impulses reach the central nervous system from the uterus through the posterior roots of the tenth, eleventh, and twelfth thoracic nerves, the first lumbar, and the second, third, and fourth sacral nerves.

The numerous **lymph-vessels** coming from the body of the uterus join those from the ovary,

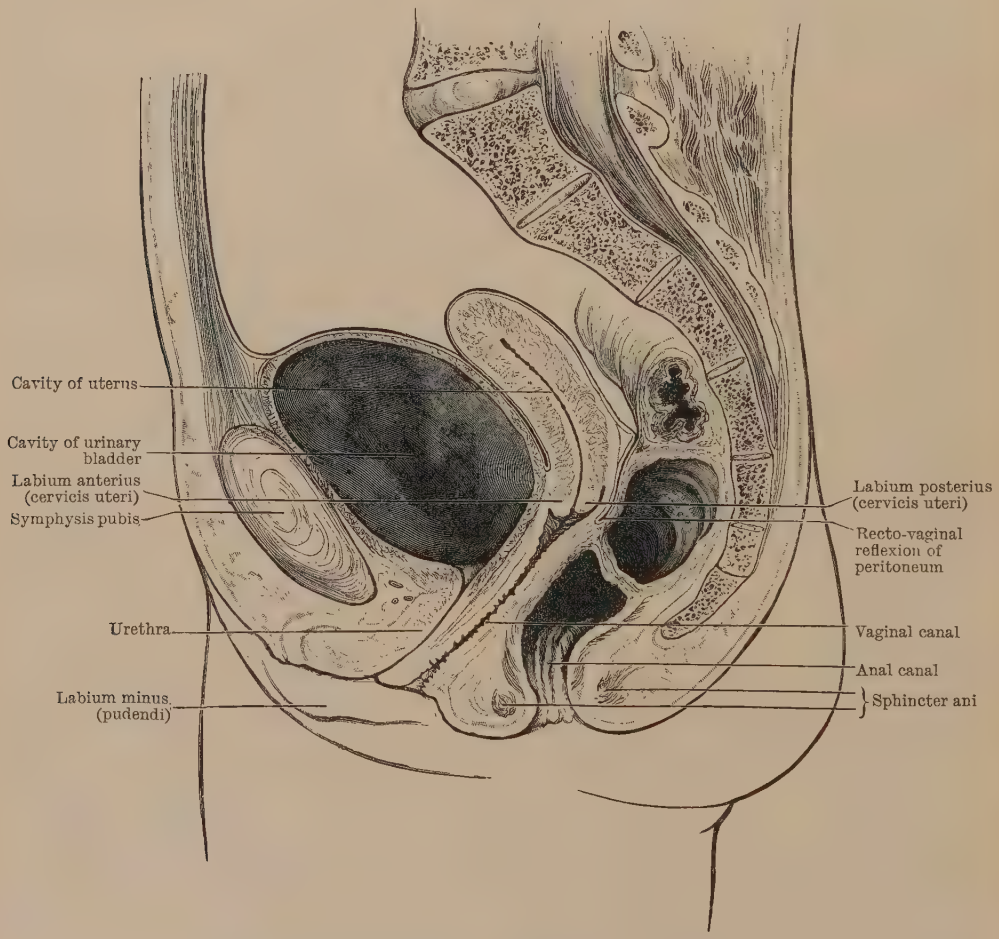

FIG. 1005.—MEDIAN SECTION OF THE PELVIS IN AN ADULT FEMALE.

The cavity of the uterus is indicated diagrammatically.

and end for the most part in the lumbar lymph-glands. Along the course of the round ligament of the uterus there are a few lymph-vessels which establish a connexion between the lymph-network surrounding the uterus and the inguinal lymph-glands. The lymph-vessels from the cervix uteri end in the gland placed near the bifurcation of the common iliac artery.

VAGINA.

The **vagina** is a passage about three inches in length, open at its lower end, and communicating above with the cavity of the uterus. The passage is directed downwards and forwards, describing a slight curve which is convex backwards. The axis of the vagina forms with that of the uterus an angle which is open forwards. This angle is usually somewhat greater than a right angle, but varies with the condition of the neighbouring viscera (p. 1302). The vagina is widest

at its upper end (Fig. 1006), and normally its anterior and posterior walls are in contact. In transverse section the lower part is usually an H-shaped cleft, the middle part a simple transverse slit, while the lumen of the upper portion, into which the cervix uteri projects, is more open. The lower part of the cervix uteri has the appearance of entering the vagina through the upper portion of its anterior wall (Fig. 1005). As more of the posterior than of the anterior part of the cervix

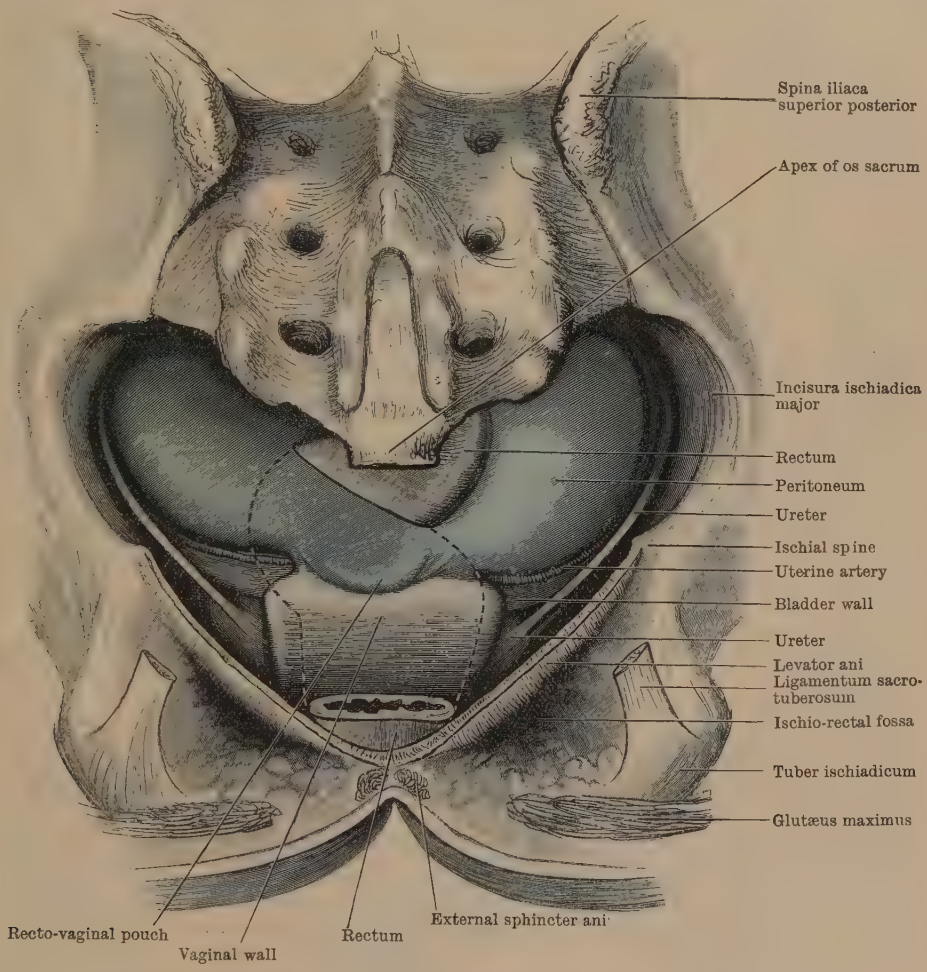

FIG. 1006.—POSTERIOR ASPECT OF THE VAGINA, THE BASE OF BLADDER, AND THE RECTO-VAGINAL POUCH OF PERITONEUM.

The coccyx and the ligamentum sacro-tuberosum and ligamentum sacro-spinosum, together with the muscles attached to them, have been removed. The levatores ani have been separated along the median raphe, and drawn laterally. A considerable portion of the rectum has been removed, but the position which it occupied is indicated by the dotted lines. The peritoneum is indicated by a blue colour. The recto-vaginal pouch is probably not quite so deep as usual. The triangular interval between the ureter and uterine artery was filled by a mass of fibro-muscular tissue, forming the lateral cervical ligament of the uterus.

projects into the vagina, a deeper recess is formed between the vaginal wall and the cervix behind than in front or laterally. The term *anterior fornix* is often applied to the recess in front; *posterior fornix* to the deeper recess behind; and *lateral fornix* to the recess on each side of the cervix uteri, between it and the wall of the vagina. The *anterior* wall of the vagina is shorter than the *posterior*, the former being about three inches in length, the latter about three and a half inches. At its lower end the vagina opens into the **pudendal cleft**, the opening being situated behind the orifice of the urethra and the clitoris, and between the labia minora. The opening is partly closed in the virgin by a thin crescentic or

annular fold, called the **hymen**, torn fragments of which persist round the opening, as the **carunculæ hymenales**, after the fold itself has been ruptured.

Relations of the Vagina.—The anterior wall of the vagina in its upper part lies against the fundus of the bladder, but is separated from it by loose connective tissue. Lower down, the anterior wall in the median plane is intimately connected with the urethra (Fig. 1005). The posterior wall in its upper portion is covered for a distance of about a quarter of an inch by the peritoneum, which here forms the anterior boundary of the deepest part of the recto-uterine pouch. The depth to which the peritoneum of this pouch descends practically corresponds to the level of the ischial spines. Lower down, the posterior wall lies close against the rectum, from which it is separated by a layer of connective tissue. As, however, the orifice of the vagina is approached, the rectum and vagina become separated by a considerable interval, which is occupied by a mass of fibrous and fatty tissue, often called the "perineum" or "perineal body." At the sides the vagina is supported by the levatores ani muscles. The terminal part of the ureter lies not far from the side wall of the upper part of the vagina, as it passes from above and behind downwards, medially and a little forwards to reach the bladder. Near its termination the vagina pierces the inferior fascia of the uro-genital diaphragm, and is related on each side to the bulbus vestibuli, the larger vestibular gland, and the bulbo-cavernosus (sphincter vaginæ) muscle.

Structure of the Vagina.—The vaginal wall has a distinct **muscular coat**, composed of unstriped muscle fibres, most of which are longitudinally disposed. Towards the lower end of the passage circularly disposed bundles of striped muscle fibres, some of which are continuous with those forming a part of the urethral wall, are found in the muscular coat. The thick **mucous coat**, which has a stratified scaly epithelium, is corrugated, and presents a number of transverse ridges or elevations known as vaginal rugæ. In addition to these transverse rugæ, a slightly marked longitudinal ridge, or column, is to be seen on the anterior and on the posterior wall of the vagina. These receive the name **columnæ rugarum**, and, like the transverse rugæ, are best seen in young subjects and in the lower part of the vagina. The urethral canal lies in close relationship to the anterior column of the vagina in its lower part, and hence this portion of the anterior column is sometimes called the **carina urethralis**.

Between the muscular and mucous coats is a thin layer of vascular tissue resembling erectile tissue.

Within the tunica mucosa are to be found small collections, or nodules, of lymphoid tissue.

The vaginal wall is surrounded by a layer of loose vascular connective tissue containing numerous large communicating veins.

The **blood-supply** of the vagina is for the most part derived from the vaginal artery, the vaginal branch of the uterine artery, the vaginal branches of the middle hæmorrhoidal artery, and from the branches of the internal pudendal. The **veins** form a plexus surrounding the vaginal wall, and drain their blood into the tributaries of the hypogastric.

The **lymph-vessels** from the upper part of the vagina join the external iliac and hypogastric groups of glands, while those from the lower part end in the superficial inguinal glands.

The **nerves** of the vagina are derived from the plexus utero-vaginalis and from the plexus vesicalis. Other fibres are derived directly from the third and fourth sacral nerves.

THE FEMALE EXTERNAL GENITAL ORGANS. (PUDENDUM MULIEBRE.)

The term **pudendum**, or **vulva**, is applied collectively to the female external genital organs, *i.e.* to the labia majora and the structures which lie between them.

Labia Majora.—The **labia majora** represent the scrotum in the male, and form the largest part of the female external genital organs. They form the boundaries, on each side, of the **rima pudendi**, or *uro-genital cleft*, into which the urethra and vagina open. Each labium is a prominent rounded fold of skin, narrow behind where it approaches the anus, but increasing in size as it passes forwards and upwards to end in a median elevation, the **anterior commissure**, or *mons pubis*. The mons pubis lies over the symphysis pubis, and, like the labia majora, it is composed chiefly of fatty and areolar tissue, and is covered with hair. The lateral convex surface of each labium majus is covered by skin containing numerous sebaceous glands and resembling that of the scrotum in the male, but the medial, flatter surface is smooth, and presents a more delicate integumentary covering.

In some cases the posterior narrow ends of the labia majora are connected across the middle line, in front of the anus, by a slight transverse fold—the **posterior commissure**.

Usually, the labia majora are the only visible parts of the external genital organs, since they are in contact with one another, and completely enclose the structures within the pudendal cleft.

The round ligament of the uterus ends in the fatty tissue of the labium majus. The superficial subcutaneous tissue resembles that of the scrotum, but contains no muscular fibres.

The **nerve-supply** corresponds with that of the scrotum, the anterior part of each labium being supplied by the branches of the ilio-inguinal nerve, and the posterior part by branches from the pudendal and by the perineal branch from the posterior cutaneous nerve of the thigh. The **blood-vessels** of the labia majora are derived from the external pudendal branches of the femoral and from the perineal branches of the internal pudendal vessels.

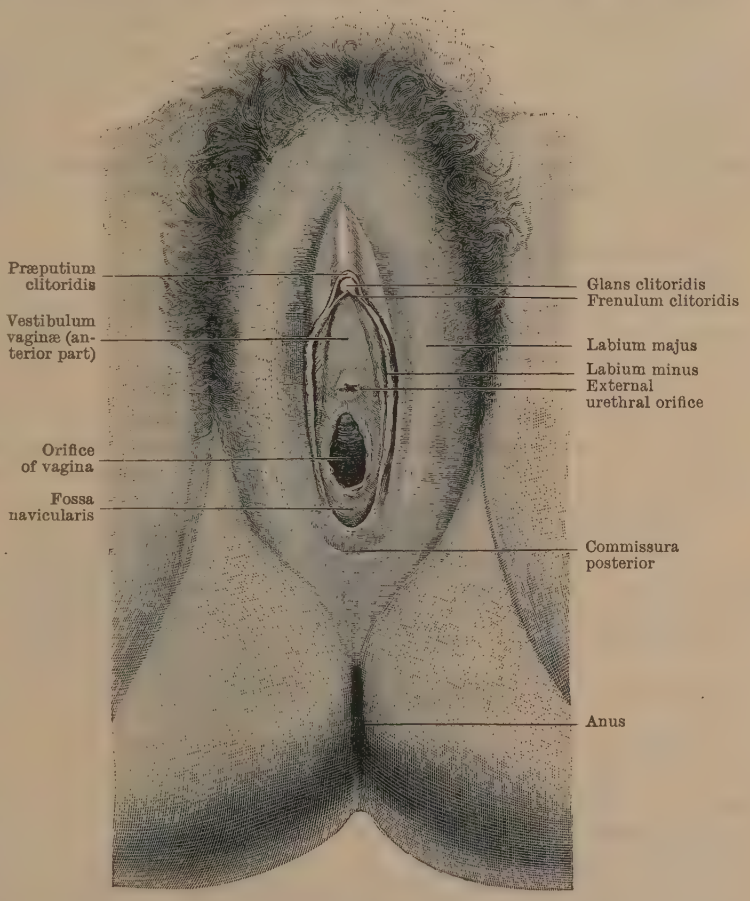

FIG. 1007.—FEMALE EXTERNAL GENITAL ORGANS.
The frenulum labiorum is seen stretching across behind the fossa navicularis and in front of the posterior commissure. The ducts of the larger vestibular glands open in the intervals between the vaginal orifice and the medial edges of the labia minora.

Labia Minora.—The **labia minora** are a pair of much smaller and narrower longitudinal folds, usually completely enclosed within the cleft between the labia majora. Diminishing in size, and becoming less marked in their posterior parts, the labia minora end by gradually joining the medial surfaces of the labia majora. In the young subject, a slightly raised transverse fold is usually seen connecting the posterior ends of the labia minora; to this fold the term **frenulum labiorum pudendi** or **fourchette** is applied. Traced forwards, each labium minus divides into two portions, a lateral and a medial. The lateral portions of the two labia unite over the glans clitoridis, and form for it a fold or covering called the **præputium clitoridis**. The medial portions, uniting at an acute angle, join the glans and form the **frenulum clitoridis**. The skin of the labia minora resembles the integument on the medial or deep surface of the labia majora, being smooth, moist, and pink in colour. The medial surfaces of the labia minora are in contact with one another; their lateral surfaces are applied against the medial aspects of the labia majora.

The openings of the urethra and vagina are placed in the median plane, in the interval between the labia minora, which must be separated to bring them into view.

Vestibulum vaginæ.—The *vestibule* is the name applied to the cleft that lies between the labia minora and behind the glans clitoridis. In its floor are the openings of the urethra, the vagina, and the minute ducts of the larger vestibular glands.

The **fossa navicularis** is the part of the vestibule placed behind the vaginal opening and in front of the frenulum labiorum pudendi.

The **external urethral orifice** lies immediately in front of that of the vagina, and is about one inch behind the glans clitoridis. The opening has the appearance of a vertical slit, or of an inverted V-shaped cleft, the slightly prominent margins of which are in contact. Sometimes on each side of the urethral orifice there may be seen the minute opening of the ductus paraurethralis (see p. 1270).

The **orifice of the vagina** lies behind and below the orifice of the urethra. The appearance of the opening varies with the condition of the **hymen**—a membrane which in the young subject partly closes the aperture. When the hymen is intact the opening is small, and is seen only when the membrane is put on the stretch. When the hymen has been ruptured the opening is much larger, and round its margins are often seen small projections—**carunculæ hymenales**—which are to be looked upon as persistent fragments of the hymen.

The **hymen** is a thin membranous fold, partially closing the lower end of the vagina, and perforated usually somewhat in front of its middle point. The position of the opening gives the fold, when stretched, a crescentic appearance. The opening in the hymen is sometimes cleanly cut, sometimes fringed. The membrane is not stretched tightly across the lower end of the vagina, but is so ample that it projects downwards into the rima pudendi, and the parts of its upper surface are in contact with one another on each side of the opening. The opening is thus a median slit whose margins are normally in contact. The upper surface of the hymen is directly continuous with the vaginal wall, and on it are to be seen slight ridges continuous with the vaginal rugæ.

Developmentally the hymen appears to be a portion of the vagina.

On each side of the vaginal opening, and close against the medial side of the attached margin of the labium minus, is the minute opening of the duct of the **greater vestibular gland** (Bartholin). This is usually just large enough to be visible to the unaided eye.

Numerous minute mucous glands, the **lesser vestibular glands**, open on the surface of the mucous membrane of the vestibule, between the urethral and vaginal orifices.

Clitoris.—The **clitoris** is the morphological equivalent of the penis, and is composed of a body and two crura. Upon the summit of the body is a minute glans. Unlike the penis, the clitoris is not traversed by the urethra.

The **corpus clitoridis** is composed for the most part of erectile tissue resembling that of the penis in the male. It is about an inch or an inch and a half in length, and is bent upon itself, forming an angle open downwards. The body of the clitoris tapers towards its distal end, which is covered by the glans clitoridis. The organ is enclosed in a dense fibrous coat, and is divided by an incomplete **septum** into two symmetrical and somewhat cylindrical portions, the **corpora cavernosa clitoridis**. These represent the corpora cavernosa penis of the male, and diverge from one another at the root of the clitoris to form the **crura clitoridis**. A fibrous suspensory ligament passes from the body of the clitoris to the symphysis pubis (Fig. 1008).

The **glans clitoridis** is a small mass of erectile tissue which is fitted over the pointed end of the body. It possesses, like the glans penis, which it represents, a very sensitive epithelium. The **præputium**, or fold of skin which covers it, and the **frenulum clitoridis**, which is attached to it inferiorly, are continuous with the labia minora (Fig. 1007).

The **crura clitoridis** diverge from the body posteriorly, and are attached to the sides of the pubic arch. Each is continuous with one of the corpora cavernosa, and has a firm fibrous sheath, which is covered by the corresponding ischio-cavernosus. In structure the crura and body of the clitoris resemble the corpora cavernosa penis, while the glans more closely resembles the bulbus vestibuli,

with which it is continuous through a structure known as the pars intermedia (Fig. 1008).

In the seal and some other animals, a bone, which represents the os penis of the male, is developed in the septum of the clitoris. This bone receives the name *os clitoridis.*

The **arterial supply** of each crus is a special branch from the internal pudendal. The glans is supplied by the dorsal artery of the clitoris.

The **nerve-supply** of the clitoris is derived partly from the hypogastric sympathetic plexus and partly from the dorsal nerves of the clitoris, which are branches of the pudendal nerves.

Bulbus Vestibuli.—The **bulb of the vestibule** is a mass of erectile tissue, in the female, which corresponds developmentally to the corpus cavernosum urethræ of the male. In the female the fusion of the two halves of this structure is not nearly so complete as in the male, for the vagina and urethra separate the bulbus vestibuli into right and left portions which are only slightly connected in front by a narrow median part called the *pars intermedia.* Each half of the bulb is thick and massive posteriorly, and more pointed in front, where it joins the pars intermedia. It rests against the lateral wall of the vagina, and upon the superficial aspect of the inferior fascia of the uro-genital diaphragm. It represents one-

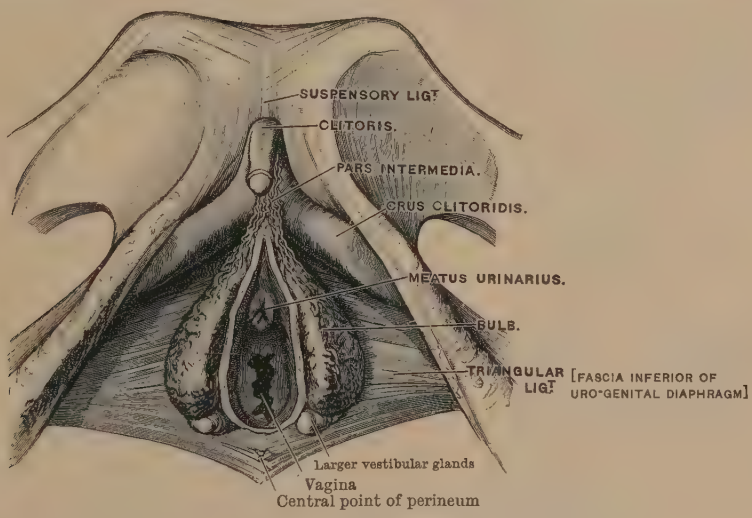

FIG. 1008.—DISSECTION OF FEMALE PERINEUM TO SHOW THE CLITORIS, THE BULB OF THE VESTIBULE, AND THE LARGER VESTIBULAR GLANDS. (D. J. Cunningham.)

half of the corpus cavernosum urethræ of the male. Superficially it is covered by the bulbo-cavernosus muscle. The pars intermedia lies above the opening of the urethra, and becomes continuous with the tissue of the glans clitoridis.

The bulb of the vestibule is for the most part composed of minute convoluted blood-vessels, held together by a very small amount of connective tissue. These vessels frequently anastomose with one another, and those of each half communicate with the vessels of the pars intermedia and the glans clitoridis.

The **blood-supply** of the bulb is derived, on each side, from a special branch of the internal pudendal.

GLANDULÆ VESTIBULARES MAJORES.

The **greater vestibular glands** or *glands of Bartholin* are placed one on each side of the lower part of the vagina, and represent the bulbo-urethral glands in the male. They are often overlapped by the posterior ends of the bulbus vestibuli, and are covered by the bulbo-cavernosus muscle. Each is about the size and shape of a small bean, and possesses a long slender duct which opens into the vestibule in the angle between the attached border of the labium minus and the vaginal opening.

DEVELOPMENT OF THE URO-GENITAL ORGANS.

The Uro-genital Passages.

General Account.—In tracing the developmental history of the uro-genital passages we may for convenience begin with an embryo of about 2½ mm. in length. At this time a duct, which runs in a longitudinal direction, and occupies a position on the lateral side of the protovertebral somites, begins to develop on each side of the body. With the exception of the anterior portion of the cloaca and the proximal part of the allantois, this duct, which has received the name of **primary excretory** or **Wolffian duct**, is the earliest formed structure from which, or in connexion with which, the parts of the adult uro-genital system arise.

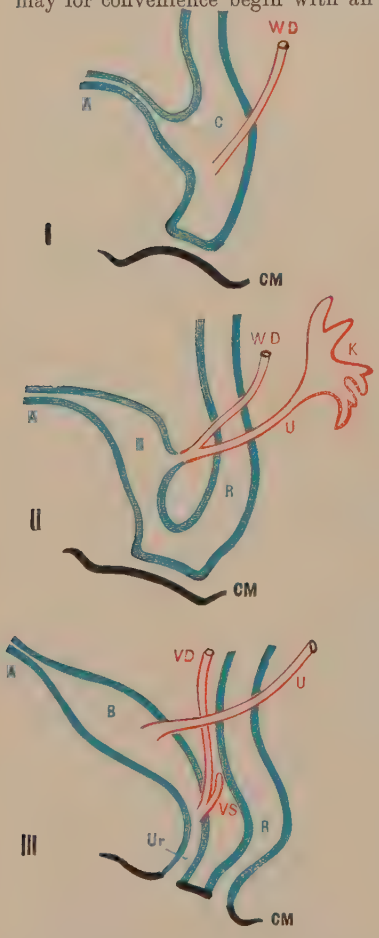

Fig. 1009.—Diagram to illustrate the Manner in which the Ureter, the Ductus Deferens, and the Urinary Bladder arise in the Embryo.

The structures developed from the cloaca are indicated in blue, those from the Wolffian duct in red, and the ectoderm in black.

The manner in which the rectum and bladder become separated and acquire openings into the ectodermal cloacal fossa is shown in II. and III. (A. H. Young and A. Robinson.)

A.	Allantois.	R.	Rectum.

C.	Cloaca.	U.	Ureter.
CM.	Ectoderm of cloacal fossa.	VD.	Ductus deferens.
		VS.	Seminal vesicle.
K.	Pelvis of kidney.	WD.	Wolffian duct.

The Wolffian duct serves as the canal, or duct, for the primitive excretory organs—the pronephros and the mesonephros of the embryo. With the atrophy of these the duct suffers modification, yet both sexes in the adult possess structures which have their embryonic origin from the Wolffian duct. In the male the **duct of the epididymis**, the **ductus deferens**, and the **ejaculatory duct**, are to be looked upon as directly developed from the Wolffian duct of the embryo; while in the female the **longitudinal duct of the ep-oöphoron** and the **vesicular appendices** are rudimentary structures having a like origin. The **ureter** and its **pelvis** arise in both sexes as an outgrowth from the Wolffian duct. In the male the **vesicula seminalis** is developed as a diverticulum of the Wolffian duct.

The primitive excretory organs, the **pronephros** and the **mesonephros**, develop in connexion with the anterior part of the Wolffian duct (p. 1311), and, during the early life of the embryo, are important structures. Even in the embryo, however, the pronephros soon becomes vestigial and it is replaced by the far more important mesonephros. With the development of the permanent kidney the mesonephros atrophies, yet some of its tubules persist in the adult. The **ductuli efferentes**, the **ductuli aberrantes** and the rudimentary **paradidymis** (organ of Giraldés) in the male, and the rudimentary tubules of the **ep-oöphoron** and of the **par-oöphoron** in the female, are structures which owe their origin to the tubules of the mesonephros.

Soon after the formation of the Wolffian ducts two other longitudinally disposed canals, called the **Müllerian ducts**, are developed. These open at their cephalic ends into the body cavity, and at their caudal ends, unlike the Wolffian ducts, they unite with one another in the median plane. From them are formed, in the female—the **uterine tubes**, the **uterus**, and the **vagina**; and in the male—the **appendices** of the testis and the **utriculus prostaticus**.

The Wolffian and Müllerian ducts open at their caudal ends into the ventral or uro-genital part of the **cloaca**, which in the course of development becomes transformed into the **bladder** and the **uro-genital canal** of the embryo. The developing ureter at first arises as a diverticulum from the Wolffian duct, at a short distance from the point where the latter joins the cloaca. Soon, however, the ureters acquire independent openings into the cloaca, which become gradually shifted further from one another and from those of the Wolffian ducts. The ureters are now found to open into the anterior portion of the cloaca which lies nearer to the head of the embryo than the part with which the Wolffian ducts are connected. This cephalic portion of the anterior subdivision of the cloaca which receives the ureters becomes the bladder and the upper part of the urethra. The caudal part, lying below the level of the entrance of the Wolffian ducts, is called the uro-genital canal and is represented in the adult male by the lower part of the prostatic and by the membranous portions of the urethra; in the female by the lower part of the urethra and the part of the uro-genital fissure which immediately surrounds the openings of the urethra and vagina (Figs. 1016, 1017). The united Müllerian ducts open into the lower part of the cloaca or

uro-genital canal between the Wolffian ducts of opposite sides. In the male the position of this opening, which is represented in the adult by the orifice of the utriculus prostaticus, remains almost unchanged; in the female, on the other hand, a downgrowth from the fused Müllerian ducts gives origin to a new passage, the vagina, which establishes an opening behind that of the urethra in the uro-genital fissure of the adult.

After the complete separation of the cloaca into anterior or uro-genital and posterior or rectal subdivisions, the rectum establishes a communication with the exterior in the floor of the shallow depression known as the ectodermal cloacal fossa. At a little later time the uro-genital canal also joins this fossa at a point in front of the opening of the rectum. The ectodermal cloacal fossa lies in front of the vestigial tail, and extends forwards as far as a tubercle known as the **cloacal tubercle**, which later gives rise to the **genital eminence** and a pair of elevations called the **labio-scrotal folds**. The genital eminence becomes converted into the clitoris or penis according to the sex. The labio-scrotal folds extending backwards on each side form the labia majora of the female, and, fusing posteriorly, give rise to the scrotum in the male. In the female the slit-like opening of the uro-genital canal retains its position, and its margins becoming elongated, form the labia minora. The vaginal opening arises, as we have seen, by a downgrowth of the fused Müllerian ducts which lies in front of the rectum and behind the primitive uro-genital canal. The latter becomes the urethra in the female. In the male the slit-like opening of the uro-genital canal is prolonged anteriorly by an active growth at the base of the genital eminence, and its margins uniting, give rise to the penile portion of the urethra.

The Wolffian Duct and Embryonic Excretory Organ.

The Wolffian Duct.—The Wolffian duct arises in the mesoderm, about the fifteenth day, as a solid cord of cells occupying a position immediately to the lateral side of the protovertebral somites and to the medial side of the body cavity (Fig. 1010). When first recognised the duct lies immediately beneath the ectoderm, and as it grows backwards to reach the cloaca it is often found to be intimately connected with the ectoderm. This close connexion of the duct with the ectoderm, in the early stages, is by some authorities supposed to indicate a primitive ectodermal origin of the canal, but by others, and apparently with more reason, to be a trace of the opening of ducts on the surface of the body, such as exists in connexion with the excretory organs of lower animals. During the third week the cellular cord which represents the Wolffian duct acquires a lumen, and about the end of the same week the duct in its growth reaches the cloaca. As soon as the cloaca has become divided into dorsal and ventral subdivisions, the Wolffian duct is seen to end in the cephalic part of the ventral subdivision, which becomes the bladder and uro-genital canal (Fig. 1012).

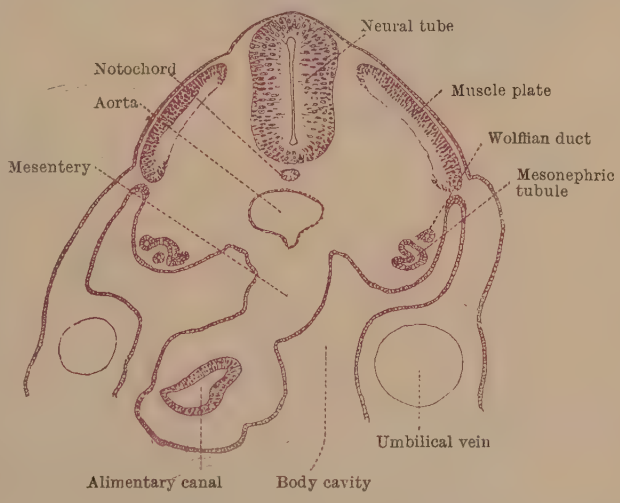

Fig. 1010.—Transverse Section through the Trunk of a Human Embryo of about 5 mm. Length.

The **mesonephros** or **Wolffian body** is developed in the mesoderm of the "intermediate cell mass," immediately adjoining the Wolffian duct, and consists of a number of transversely arranged canals or tubules, each of which opens by one end into the Wolffian duct, while its other extremity ends blindly. These transverse tubules, like the canal into which they open, are at first solid cellular structures, and only later acquire a distinct lumen. Increasing rapidly in size and number, the tubules become twisted and tortuous, and the blind end of each dilates to form a capsule invaginated upon itself and containing a bunch of capillary blood-vessels similar to the glomeruli of the adult kidney. It would appear that primitively one tubule is developed in the portion of the intermediate cell mass (nephrotome) corresponding to each mesodermic somite, but, in higher vertebrates at all events, such a correspondence between the number of somites and the number of tubules cannot be demonstrated. In the posterior part of the mesonephros the number of tubules is very numerous, and greater than the number of segments in this region. The tubules of the mesonephros arise in all segments from the sixth cervical to the third lumbar. The tubules in the anterior part atrophy and disappear at a very early time, even while others are being formed towards the caudal end of the embryo. When at its greatest development (fifth to eighth week) the mesonephros forms a relatively large glandular mass, composed of tubules resembling in a general way those of the adult kidney. At this time it projects into the dorsal part of the body cavity, and extends from the region of the liver to the caudal end of the body cavity. Along its lateral aspect lies the Wolffian duct.

As the permanent kidney, or metanephros, is developed the mesonephros atrophies; a portion of it, however, is retained *in the male*, and forms the excretory apparatus of the testis.

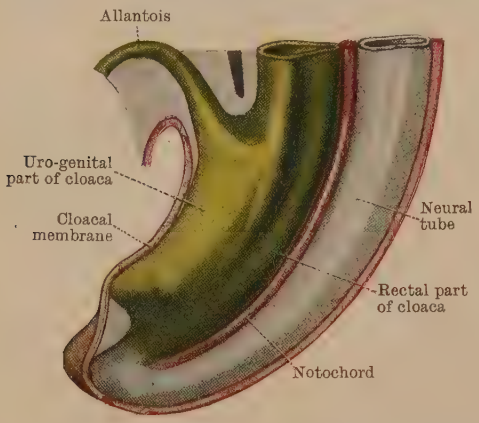

FIG. 1011.—TAIL END OF HUMAN EMBRYO BEFORE THE TIME AT WHICH THE WOLFFIAN DUCTS REACH THE CLOACA. (Drawn from a model constructed by Prof. F. Keibel.)

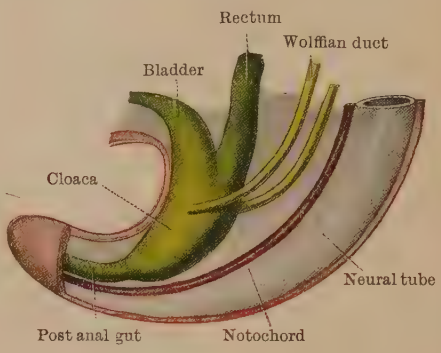

FIG. 1012.—TAIL END OF HUMAN EMBRYO. The Wolffian ducts open into the anterior part of the cloaca. (Drawn from a model constructed by Prof. F. Keibel.)

The Wolffian duct becomes the canal of the epididymis and the ductus deferens of the adult (see p. 1316). *In the female*, when the permanent kidney is formed, the mesonephros and its

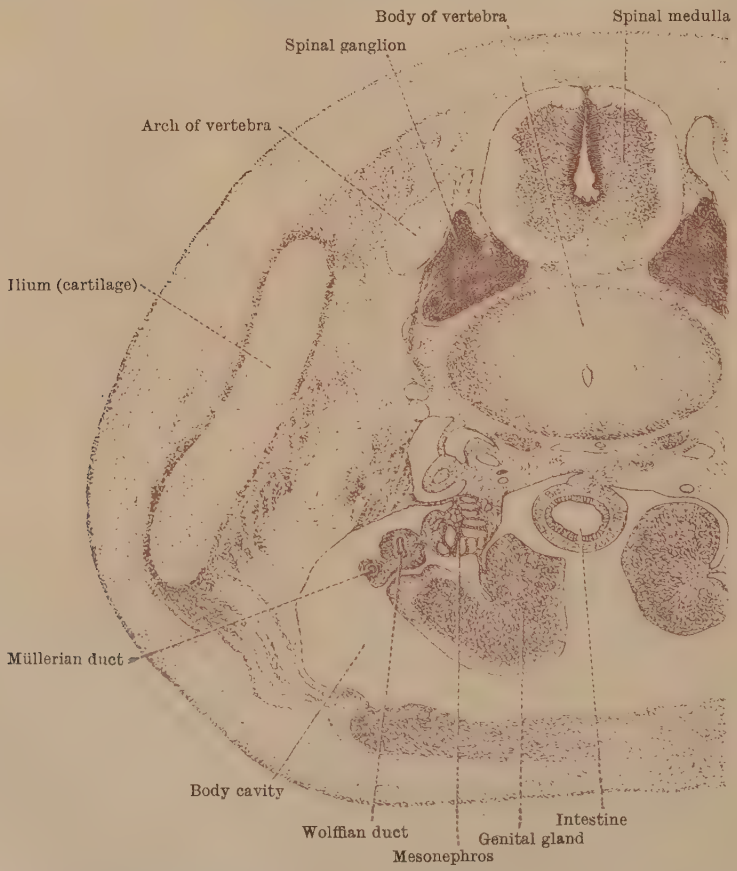

FIG. 1013.—TRANSVERSE SECTION THROUGH THE LOWER PART OF THE TRUNK OF A HUMAN EMBRYO OF ABOUT 7 WEEKS. (Specimen in the possession of Prof. J. Symington.)

duct undergo atrophy to a greater extent than in the male, and they are only represented in the adult by the vestigial structures present in the broad ligament of the uterus (see pp. 1298 and 1316).

In anamniate vertebrates—fishes and amphibia—the mesonephros persists as the excretory organ of the adult.

Pronephros.—From what is known regarding the development of lower animals, it seems certain that the Wolffian duct originally served as the duct of the still earlier excretory organ—the **pronephros**. In man the pronephros arises earlier than the mesonephros, and its tubules can only with difficulty be distinguished from those of the later appearing mesonephros. The tubules of the pronephros arise in all the segments from the fifth cervical to the third lumbar.

The Ureter and Permanent Kidney.

The ureter arises as a tubular diverticulum from the Wolffian duct close to the point where the latter joins the cloaca (Figs. 1014 and 1015). This diverticulum is seen first during the fourth week, and grows from behind forwards, dorsal to the body cavity. Even in its very early condition the portion of the outgrowth which lies nearest to the Wolffian duct, and from which the adult ureter is developed, is more slender than the distal part, which becomes branched, and grows out to form the pelvis and calyces of the ureter. From the calyces numerous collecting tubules grow out into the developing kidney and acquire connexions with the glandular or uriniferous tubules of the kidney. The uriniferous tubules of the kidney arise independently of the ureter in a backward prolongation of the tissue which, further forward, gives origin to the tubules of the mesonephros. The tissue in which the permanent kidney tubules arise lies behind the third lumbar segment. The blind distal end of each tubule soon dilates to form a capsule which, becoming invaginated on itself, encloses a tuft of capillary blood-vessels. The renal corpuscles arising in this manner are found in the human kidney as early as the eighth week.

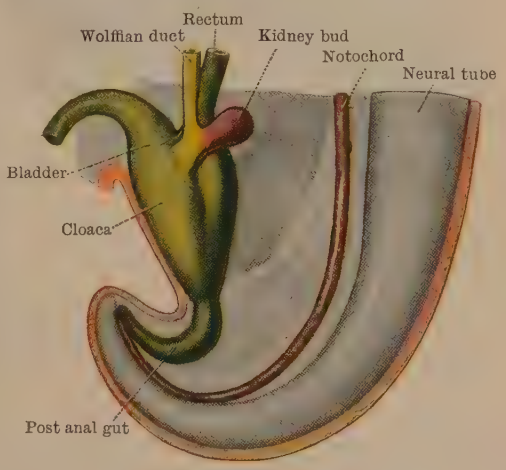

Fig. 1014.—Tail End of a Human Embryo about 25 Days Old.

The cloaca is dividing into rectal and urino-genital subdivisions. The ureter is arising as a bud from the Wolffian duct. (Drawn from a model constructed by Prof. F. Keibel.)

As regards their origin in the embryo we distinguish between the collecting tubules and their branches, and the uriniferous secretory tubules of the kidney. The former arise from the calyces of the ureter, and hence are derived from the Wolffian duct; the latter are formed in mesoderm, known as the metanephric cell mass, which is continuous at its anterior end with the tissue from which the mesonephros is derived. The short junctional tubules of the adult lie in the region where these developmentally distinct portions of the kidney unite.

As the ureter increases in length, it becomes separated from the Wolffian duct, and acquires a distinct opening into the anterior part of the cloaca nearer the head of the embryo than that of the Wolffian duct. This part of the cloaca receiving the ureters becomes the bladder. The kidney is at first a distinctly lobulated body, and shows at birth, and sometimes even in the adult, distinct traces of its original subdivision into lobules.

The metanephric cell mass, in which the uriniferous tubules arise, lies at first on the medial side of the bud-like outgrowth which represents the ureter; at a later time it comes to lie dorsally. As the ureter grows towards the head end of the embryo the cell mass which gives rise to the uriniferous tubules follows it; hence the metanephric tissue ceases to lie to the caudal end of the mesonephros. As the ureter divides to form the calyces, the metanephric cell mass becomes broken up into cap-like portions, one for each branch of the ureter, and later one for each of the collecting tubes which grow out from the calyces.

The formation of uriniferous tubules within the cell masses is continued until a few days after birth.

The Bladder.

The main portion of the bladder is formed from the superior (cephalic) part of the anterior subdivision of the cloaca. This at an early time becomes flattened dorso-ventrally, and produced laterally into two horn-like projections in the region where the Wolffian ducts open (Fig. 1015). Inferiorly it becomes constricted to form the uro-genital canal. Little by little the lower ends of the Wolffian ducts open out and are absorbed into the wall of the developing bladder, and soon it comes about that the ureters, which originally were outgrowths of the Wolffian ducts, open directly into the bladder. The openings of the ureters become shifted laterally, but the final position of the openings of the Wolffian ducts is close to the median plane in the upper prostatic part of the urethra. The bladder has therefore a double origin:—its main portion is derived from the entodermal cloaca; its smaller basal part arises from the opened-out lower ends

of the Wolffian ducts. The latter portion approximately corresponds to the trigonum vesicæ of the adult, and must be regarded as having its source from the mesoderm. The extreme cephalic end of the anterior part of the cloaca tapers gradually, and beyond the umbilicus is continuous with the allantois. This part of the cloaca loses its lumen about the fifth week, and from it is derived the fibrous cord of the **urachus** or median umbilical ligament, which in the adult reaches from the bladder apex to the umbilicus.

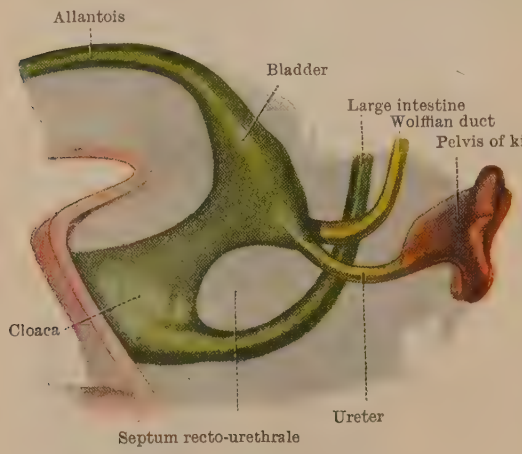

FIG. 1015.—TAIL END OF HUMAN EMBRYO ABOUT 33 DAYS OLD.

The cloaca is becoming separated into rectal and uro-genital portions by the formation of the septum recto-urethrale. The ureter has acquired a separate opening into the anterior division of the cloaca. (Drawn from a model constructed by Prof. F. Keibel.)

The cavity of the urachus is sometimes not lost so early, and in rare cases it has been found persisting in the child or adult as a pervious channel extending from the apex of the bladder to the umbilicus. Here it may open on the surface of the body.

THE MALE URETHRA.

The first part of the male urethra has an origin similar to that of the basal part of the bladder, and is derived from the ends of the Wolffian ducts (see above, p. 1310). The remaining portion, beyond the openings of the ductus deferentes of the adult, is derived from the uro-genital canal, or caudal subdivision of the anterior part of the cloaca. The uro-genital canal is early subdivided into a pelvic part lying within the future pelvis minor and a penile part which occupies the region in which the corpus cavernosum urethræ is developed. The latter part of the uro-genital canal becomes filled with closely and irregularly packed cells, which later, breaking down, re-establish the canal and give origin to a slit-like opening in the region in front of the anus. The canal for some time opens at a rhomboidal fossa situated in the groove at the base of the glans. In the glans penis a septum of densely packed cells passes forwards from this fossa and is known as the urethral septum.

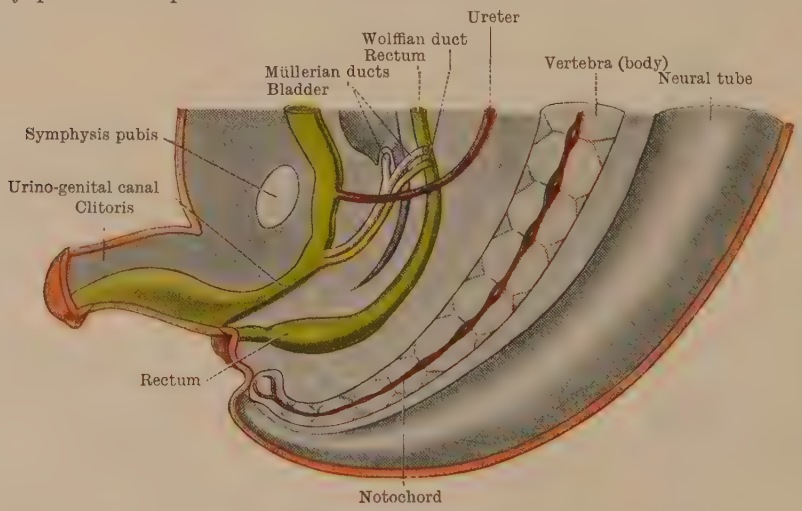

FIG. 1016.—TAIL END OF FEMALE HUMAN EMBRYO ABOUT 9 WEEKS OLD.

The rectum has acquired an opening and the entoderm of the uro-genital canal is continued into the genital eminence (clitoris). (Drawn from a model constructed by Prof. F. Keibel.)

At a later stage these cells also break down and form a groove, the lips of which unite and enclose the terminal portion of the urethra. It is doubtful if any portion of the male urethra owes its origin to the ectoderm, but there is some evidence to show that the urethral septum is to be regarded as ectodermal, in which case the part of the canal which traverses the glans must have a like origin.

THE FEMALE URETHRA.

In the female the part of the urethra near the internal urethral orifice is developed from the inferior ends of the Wolffian ducts and has an origin similar to that of the basal portion of the

bladder. The inferior part of the passage is derived from the uro-genital canal. When the uro-genital canal opens on the surface it is continued forwards as a sulcus on the genital eminence, as in the male sex. The margins of the slit-like opening do not unite, but form the labia minora of the adult, and the sulcus which appears on the glans clitoridis is closed without forming a canal. At first the fused caudal ends of the Müllerian ducts open into the uro-genital canal, but later a downgrowth, which is at first solid, establishes a connexion between these ducts and the surface immediately in front of the rectum and behind the opening of the uro-genital canal. This new connexion becomes the vagina, and the uro-genital canal the urethra. By some embryologists it is believed that a shortening and spreading out of the inferior portion of the uro-genital canal, to form a part of the uro-genital cleft of the adult, is responsible for bringing the opening of the fused Müllerian ducts to the surface. If this latter view is accepted, the female urethra corresponds to the part of the male passage which lies above the opening of the utriculus prostaticus.

The Sexual Glands.

Sexual Glands.—In the development of the sexual glands, male and female, a differentiated thickened portion of the peritoneal epithelium is first recognised. This specialised epithelium, which has received the name of **germinal epithelium**, is situated to the medial side of the mesonephros and of the Wolffian and Müllerian ducts. Here it covers a longitudinally disposed ridge or elevation called the **genital ridge**. The germinal epithelium is not strictly limited to this ridge, but extends to some extent beyond its limits. The genital ridge is soon found to have numerous epithelial cells embedded in its connective-tissue stroma which appear to originate, in both sexes, by a proliferation from the deep surface of the germinal epithelium covering the ridge. From these epithelial cells the seminiferous tubules of the male and vesicular follicles with their contained ova of the female are developed. The tissue which gives rise to the genital ridge occurs in all the body segments from the sixth thoracic to the second sacral, but the cephalic end of the ridge atrophies before the germinal epithelium can be recognised in the more caudal segments, and only about one-fourth of the ridge gives origin to the permanent sexual gland. The part of the genital ridge which persists appears to correspond to three or four segments in the region of the 4th or 5th lumbar to the 1st or 2nd sacral segments.

Fig. 1017.—The Uro-genital Passages at the Indifferent Stage of Development.

Ureter, green solid outline. Wolffian duct, green dotted outline. The origin of the vesicula seminalis is indicated. Müllerian ducts, orange. Rectum, bladder, and urino-genital canal, red.

In the male, as early as the thirty-third day, the epithelial cells embedded in the stroma of the developing testis have become arranged into a network of anastomosing cords within which certain larger cells are seen to be irregularly scattered. These larger cells have received the name of **primitive sperm cells**, and are relatively few in number. They undergo frequent division, and in the later stages are not to be distinguished from the other cells of the cords. The cellular cords undergo direct transformation into the **seminiferous tubules** of the testis, the **tubuli recti**, and the **rete testis**. At a very early stage the superficial part of the stroma of the developing testis becomes denser, and gives origin to the **tunica albuginea**. The tissue surrounding the cellular cords becomes converted into the septula testis and the mediastinum. A lumen can first be recognised in the seminiferous tubules in the seventh month. The rete testis becomes connected secondarily with the ductuli efferentes which are derived from tubules of the mesonephros, and thus the mesonephric or Wolffian duct becomes the passage for the secretion of the testis.

In the female, large epithelial cells are found in the stroma of the developing ovary, beneath the germinal epithelium, as early as the thirty-third day. These **primitive ova** are much more numerous than the primitive sperm cells of the male, and form a very characteristic feature of the developing ovary. At first they lie isolated, but later—about the fifth week—they become surrounded by other smaller cells having a like origin from the germinal epithelium. Each primitive ovum surrounded by its cells becomes a **primitive follicle**, the further development of which has already been described (p. 1296). During the later stages the epithelium has the appearance of growing down into the stroma in the form of long branching cellular processes which break up into little nests of cells to form the future follicles. The proliferation of cells from the surface epithelium goes on until the seventh month, but it is extremely doubtful if any new ova arise in later months of gestation or after birth.

The Generative Ducts.

Generative Ducts.—As has been already stated, the male ducts arise from the Wolffian and the female from the Müllerian ducts of the embryo. Both sexes at first possess well-developed Wolffian and Müllerian ducts, which are arranged in a very definite manner. The

Wolffian ducts, communicating directly with the tubules of the mesonephros, lie at first parallel to, and at a considerable distance from, one another. As they pass towards the caudal end of the embryo they approach one another, and each becomes enclosed in a fold of peritoneum called the **plica urogenitalis.** More caudally the ducts become closely approximated to each other, and are embedded in a cord-like mass of connective tissue, to which the term **genital cord** is applied. They finally open into the anterior subdivision of the cloaca (Fig. 1017).

FIG. 1018.—THE URO-GENITAL PASSAGES IN THE MALE.

Ductus deferens, dotted green outline. Ureter, solid green outline. Utriculus prostaticus, orange. Bladder and pelvic part of urethra, red. Penile portion of urethra, black.

The Müllerian ducts, opening freely into the body cavity at their cephalic ends, lie to the lateral side of the Wolffian ducts. As they are traced caudally they are crossed by the Wolffian ducts and enter the genital cord, within which they unite and form a canal, which occupies the median plane, and opens into the anterior subdivision of the cloaca, between the Wolffian ducts (Fig. 1017). The manner in which the ureters become separated from the Wolffian ducts has already been described.

Ducts in the Male.—The seminiferous tubules of the testis become connected with the Wolffian duct through a fusion of certain tubules of the mesonephros with the **rete testis.** The connexion is definitely established in the third month. The number of tubules taking part varies considerably, but corresponds to the number of **ductuli efferentes** found in the adult. The connecting tubules becoming more convoluted, just as they join the Wolffian duct, form the **lobules of the epididymis.** The **canal** cephalic part of the Wolffian duct, and the The **ductuli aberrantes** and the rudimentary **of the epididymis** is directly formed from the **ductus deferens** from the more caudal portion. tubules of the **paradidymis** are to be looked upon as persistent tubules, of a more caudal portion of the Wolffian body, which have failed to become connected with the tubules of the testis.

The **seminal vesicles** are developed in the third month as evaginations which arise from the Wolffian ducts, near their caudal extremities. Each at first has the appearance of a longitudinal groove in the wall of the ductus deferens, which closes over and becomes cut off from the main tube except at the point where, later, the duct of the seminal vesicle joins the ductus deferens.

The Müllerian ducts atrophy in the male embryo, but the appendices of the testis are vestigial remains of their cephalic portions, while the **utriculus prostaticus** represents the caudal fused portions which, in the embryo, occupy the genital cord.

Ducts in the Female.—The Müllerian ducts in the female retain their openings into the body cavity, and their cephalic portions become the uterine tubes. Their fused caudal parts, which at first join the uro-genital canal, give rise to the **uterus** and **vagina.** The manner in which the original position of the opening of the Müllerian ducts becomes shifted, by the formation of a new passage or by the shortening of the uro-genital canal, has already been mentioned (p. 1315). The final position of the opening is in the uro-genital cleft of the adult.

FIG. 1019.—THE URO-GENITAL PASSAGES IN THE FEMALE.

Derivations of the Müllerian ducts, orange. Ureter, green solid outline. The ep-oöphoron is indicated in green near the opening of Müllerian duct and near the ovary.

The vaginal portion of the fused Müllerian ducts is at first relatively very short, and at the point where it opens into the uro-genital canal a slight fold appears, which is the future **hymen.** The vagina increases rapidly in length as its opening moves downwards towards the

uro-genital cleft. In the human embryo during the third month the closely applied Müllerian ducts, which higher up have fused to form the uterus, are represented at their inferior ends by a pair of rapidly elongating solid cellular cords, which at a later stage break down to form the vagina.

The Wolffian ducts and the mesonephros atrophy in the female, but traces of them are to be found in the ep-oöphoron and par-oöphoron of the adult. In the fœtus the Wolffian duct can be traced along the side of the uterus as far as the upper end of the vagina.

Prostate.—The glandular portion of the prostate arises as a series of solid outgrowths from the epithelium of the uro-genital canal during the third month. The outgrowths, which are at first simple, become branched and finally acquire a lumen. They are arranged in three groups—an upper and a lower dorsal, and a ventral group. The glands of the ventral group soon become reduced in number and often completely disappear; those of the upper dorsal group form the chief part of the gland.

The prostatic glands arise in both sexes, but in the female, where they are known as para-urethral glands, they are few in number and not densely packed as in the male. The muscular tissue of the prostate is derived from the muscular wall of the urethra.

The **bulbo-urethral glands** arise in the third month, and appear to be developed from the epithelium of the uro-genital canal.

The **larger vestibular glands** in the female arise as epithelial outgrowths in the same manner as the bulbo-urethral glands.

External Genital Organs.

The external genital organs are developed in the region of the ectodermal cloacal fossa, and those of the male and female cannot be distinguished from one another in the earlier stages. The

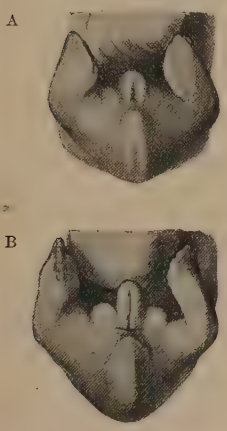

Fig. 1020.—External Genital Organs, Human Embryos. Indifferent stage. A. Embryo of 20 mm. B. Slightly larger.

The genital eminence and the labio-scrotal folds are well seen.

Fig. 1021.—External Genital Organs, Male Embryo.

Formation of scrotum. The labio-scrotal folds, formerly best marked at the sides of the genital eminence, have grown backwards and united behind the primitive uro-genital opening, to form the raphe scroti. The genital folds embrace the base of the genital eminence or penis. The glans is very prominent.

Fig. 1022.—External Genital Organs, Male Embryo.

Behind the glans penis the urethra opens in a diamond-shaped fossa in the dorsal wall of which the median raphe ends. The prepuce is formed behind the constriction which marks off the glans, and as it grows forwards the constriction disappears.

A little horn-like process of epithelium is present on the summit of the genital eminence.

fossa at first extends on the ventral aspect of the body almost from the tail to the umbilical cord. At its cephalic end is a tubercle known as the **cloacal tubercle**, and behind lies the coccygeal tubercle. Immediately in front of the latter the anus is formed, and between this opening and the cloacal tubercle the uro-genital canal opens on the surface by a median slit-like aperture, the **primitive uro-genital opening.**

The cloacal tubercle early becomes subdivided into an apical **genital eminence** which occupies the middle line and lies at the cephalic end of the slit-like uro-genital opening, and a basal portion which lies nearer to the umbilicus and also curves round the sides of the genital eminence. At a later time the basal part is continued to form a prominent fold on each side of the ectodermal cloacal fossa. These folds are called the labio-scrotal folds and, *in the female*, give rise to the labia majora. The lateral margins of the primitive uro-genital opening give origin to the labia minora, and the genital eminence becomes the clitoris. On the clitoris at a very early date a relatively large glans is marked off by a surrounding sulcus. *In the male* the scrotal folds grow backwards, and meeting behind the primitive uro-genital opening, fuse together. In this way the opening is pushed forwards. The genital eminence elongates rapidly

owing to a growth at its basal part, and a sulcus which is formed on its cloacal aspect gradually becomes converted into a canal by the closure of the lateral lips of the primitive uro-genital opening. Soon the uro-genital opening is found to lie nearer the apex than the base of the eminence, which has now given rise to the penis. For some time the opening in the male lies at the base of the glans penis and is somewhat rhomboidal in outline. At a later time, owing to the breaking down of a dense septum of epithelial cells which appears within the glans, a sulcus and finally a canal arises within this part of the penis and thus the terminal part of the urethra is formed. When the opening at the base of the glans is closed the continuous urethral passage is established. The main portion of the urethra is entodermal in origin, but there is some evidence to indicate that the part which traverses the glans has its origin from the ectoderm.

THE MAMMARY GLANDS.

The **mammæ** or breasts are accessory organs connected with the female reproductive system. Each gland is situated in the superficial fascia covering the anterior aspect of the thorax, and usually extends from the level of the second or third to that of the sixth rib. The hemispherical projection formed by the gland lies upon the superficial aspect of the pectoralis major and to a less extent upon the serratus anterior muscle. Near the summit of each mammary elevation, and usually at the level of the fourth or fifth rib, is placed the wart-like **nipple** or papilla mammæ, which is pierced by the minute openings of the lactiferous ducts and is surrounded by a coloured circular area of skin called the **areola**. The skin covering the nipple is thrown into numerous wrinkles, and on the areola exhibits many minute rounded projections due to the presence of underlying cutaneous glands. These **areolar glands** are considered to represent rudimentary portions of the mamma. The colour of the nipple and areola varies with the complexion of the individual, but in young subjects they are usually of a somewhat rosy-pink colour, which changes to a deep brown during the second and third months of first pregnancy. Also, during pregnancy, the areola increases in size and its glands become more marked. The nipple contains a considerable number of unstriped muscle fibres, and becomes firmer and more prominent as a result of mechanical stimulation.

FIG. 1023.—DISSECTION OF THE MAMMA.

The size and appearance of the mammæ vary much, not only in the different races of mankind, but also in the same individual under different conditions. In the young child the mammæ are small, and there is little difference between those of the male and female. Their growth is slow until the approach of puberty, and then the female mammæ increase rapidly in size. At each pregnancy the mammæ become large, and they attain their greatest development during lactation. The size of the mamma depends partly on the amount of superficial fat and partly on the amount of glandular tissue present.

Structure of the Mamma.—The mamma is composed of a mass of glandular tissue traversed and supported by strands of fibrous connective tissue, and covered by a thick layer of fat. The glandular tissue, to which the term **corpus mammæ** is applied, forms a somewhat conical mass, the apex of which corresponds to the position of the nipple, while its base is loosely connected to the fascia covering the pectoralis major and serratus anterior muscles. In section the corpus mammæ is readily distinguished from the surrounding fat by its firmer consistency and by its pinkish-white colour. The corpus mammæ is composed of lobes and lobules, and

its superficial aspect and edges are very uneven, the inequalities of its surface being filled up by processes of the fatty tissue which forms a covering for the gland. This fatty covering is incomplete beneath the areola, and here the lactiferous ducts pass into the nipple. The gland is composed of fifteen to twenty **lobes**, which radiate from the nipple, each lobe being quite distinct from the others and possessing its own duct. The lobes are subdivided into secondary lobes and lobules, bound together and supported by a considerable amount of connective tissue which forms the **stroma** of the gland.

The alveoli of the gland and the secretory epithelium lining them vary much under different conditions. At puberty the corpus mammæ is composed chiefly of connective-tissue stroma and the ducts of the gland. At this time the alveoli are small and few in number. During lactation, when the gland is fully functional, the alveoli are enlarged, distended with fluid, and much more numerous. The epithelial cells are cubical and filled with fat globules. When the gland is not secreting, the alveoli become small and reduced in number, while the cells of the lining epithelium, which are now small and glandular, do not contain fat globules.

The **lactiferous ducts**, passing towards the nipple, become enlarged to form small spindle-shaped dilatations, called *ampullæ*, or **sinūs lactiferi**; then becoming once more constricted, each duct passes, without communicating with its neighbours, to the summit of the nipple, where it opens.

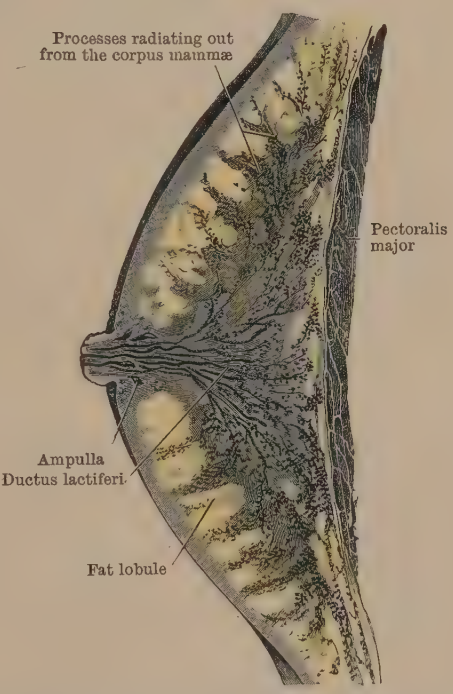

Fig. 1024.—Section through a Mammary Gland. Prepared after immersion in nitric acid as recommended by Sir Harold Stiles. (D. J. Cunningham.)

In the male subject the various parts of the mamma are represented in a vestigial condition.

The presence of milk-glands is characteristic of the class mammalia, and the number of pairs of glands in each group of animals bears some relation to the number of young usually produced at each birth.

Variations.—Asymmetry in the development of the mammæ is very common—the left mamma being very often larger than the right. Absence of one or both mammæ is a very rare abnormality, which may or may not be associated with absence of the nipples. When one nipple only is present it is usually the left. The presence of supernumerary glands or nipples is not very uncommon. The term **polymasty** has been applied to cases in which more than the normal number of mammæ are present, and **polythely** to those in which additional glands, in a vestigial condition, are represented by accessory nipples. Usually the accessory glands, or nipples, are present on the anterior aspect of the thorax, and in most instances they occur below and a little to the medial side of the normal site. When the abnormal glands are found above the normal site they generally lie further from the median plane. Much more rarely accessory glands have been found on the abdomen, in the axilla, or in some other situation, including even the dorsal aspect of the trunk. As many as three extra pairs of mammæ have been found in the same individual, and cases in which the probable representatives of mammary glands were even more numerous have been recorded. Asymmetry is very common in these abnormal structures. It is interesting to note that examples of polymasty and polythely occur in the male rather more frequently than in the female. In some women the accessory breasts have yielded milk during lactation; in most cases the abnormal organs are very rudimentary, and represented only by a minute nipple or pigmented areola. These cases of polymasty and polythely are supposed to represent a reversion to an ancestral condition, in which more than two mammary glands were normally present, and in which probably many young were produced at each birth. In this connexion it is interesting to observe that usually the accessory glands occur in positions normally occupied by mammæ in lower animals. In the course of the development of the mammæ in man, specialised areas of the epidermis, similar to those which give origin to the mammæ, have been observed both superior and inferior to the region in which the adult mammæ are developed. These areas appear to be present normally, but in most cases they disappear at an early stage in the history of the embryo. In some other mammals rudimentary mammæ may occur, as, for instance, in lemurs and in cows.

A slight functional activity of the mammary glands of the male at birth and about the time of puberty is stated to be a not very uncommon occurrence.

Vessels and Nerves of the Mamma.—The breast receives its arterial supply from the perforating branches of the internal mammary artery and from the external mammary branches of the lateral thoracic. Additional supply is sometimes derived from some of the intercostal vessels. The veins coming from the gland pour their blood into the axillary and internal mammary veins. Some small superficial veins from the breast join tributaries of the external jugular.

The **lymph vessels** of the breast are very numerous, and form extensive lymph spaces round the alveoli of the gland. These freely anastomose with the lymph vessels of the skin and more especially with the vessels of a very large anastomotic circle deep to the skin of the nipple. The lymph vessels coming from the deep parts of the mamma for the most part join the lymph glands of the axilla. They first run directly towards the deep surface of the breast, where they enter the fascial lymph vessels contained in, or lying deep to, the fascia of the pectoralis major. These fascial vessels end for the most part in the axillary glands. It is important to remember that while the majority of the lymph vessels first reach the lymph glands lying on the lateral border of the pectoralis major, some free vessels may "short circuit" to glands—(1) in the floor of the axilla, (2) along the circumflex vessels, (3) even to glands along the axillary vein. Yet other lymph vessels of the breast may reach first the glands in the costo-coracoid space. Some vessels from the medial part of the breast, following the course pursued by the perforating arteries, may join the lymph glands situated along the course of the internal mammary artery, but these vessels are fortunately often absent. It is also to be remembered that a few, probably irregular, communications exist across the middle line with the lymph vessels of the opposite breast; and further that lymph vessels from the infero-medial area of the breast regularly join the fascial lymph vessels of the upper part of the sheath of the rectus abdominis, and through these make communication with the lymph vessels of—(1) the round ligament of the liver, (2) the peritoneum generally, and ultimately with the abdominal lymph glands. The surgical importance of the facts regarding the lymphatic drainage of the breast cannot be exaggerated.

The **nerve-supply** of the gland is derived from the **intercostal nerves** of the fourth, fifth, and sixth intercostal spaces. Along the course of these nerves sympathetic filaments reach the breast from the thoracic part of the sympathetic trunk.

DEVELOPMENT OF THE MAMMÆ.

The mammæ are developed as downgrowths of the ectoderm into the underlying mesodermic tissue. In the human embryo a thickened raised area of the ectoderm can be recognised in the region of the future mamma at the end of the fourth week. This thickened ectoderm becomes depressed in the underlying mesoderm, and thus the mammary area soon becomes flat, and finally sunk below the level of the surrounding epidermis. The mesoderm, where it is in contact with this downgrowth of the ectoderm, is compressed, and its elements become arranged in concentric layers, which, at a later stage, give rise to the connective-tissue stroma of the gland. The depressed mass of ectoderm cells soon becomes somewhat flask-shaped, and grows out into the surrounding mesoderm as a number of solid processes, which represent the future ducts of the gland. These processes, by dividing and branching, give rise to the future lobes and lobules, and much later to the alveoli. The mammary area becomes gradually raised again in its central part to form the nipple. A lumen is formed in the different parts of this branching system of cellular processes only at birth, and with its establishment is associated the secretion of a fluid resembling milk, which often takes place at this time. The ampullæ appear as thickenings on the developing ducts before birth.

In those animals which possess a number of mammary glands—such as the cat and pig—the thickening of the ectoderm, which is the first indication of the development of these structures, takes the form of a pair of ridges extending from the level of the forelimb towards the inguinal region. These converge posteriorly, and at their terminations lie not far from the middle line. By the absorption of the intermediate portions the ridges become divided up into a number of isolated areas, in connexion with which the future glands arise. Somewhat similar linear thickenings of the ectoderm have also been recognised in the human embryo, and the usual positions assumed by the accessory glands when present lead us to suspect that in all probability the ancestors of man possessed numerous mammæ arranged, as in lower animals, in lines converging towards the inguinal region.

THE DUCTLESS GLANDS.

Originally by the late D. J. Cunningham, F.R.S.,
Late Professor of Anatomy, University of Edinburgh;

Revised and rewritten by A. C. Geddes, M.D., F.R.S.E.,
Professor of Anatomy, McGill University, Montreal;

Rewritten by J. T. Wilson, F.R.S.,
Professor of Anatomy, University of Cambridge.

The title, the *ductless glands* (B.N.A. glandulæ clausæ), denotes a rather diversified group of organs.

Their common character, implied in their designation as glands, is that they elaborate some special product or products. The material thus elaborated passes directly into the circulation without traversing any special channels or ducts.

These products of glandular activity are in several instances chemical substances of more or less definite composition. This is the case with the adrenin produced by the medulla of the suprarenal gland. To the same general category of gland belong the thyreoid and parathyreoid glands, the hypophysis and, probably, the pineal body. Such ductless glands are therefore organs of internal secretion in the definite chemical sense. They are frequently known as endocrine organs.

There are, however, certain other organs, ordinarily reckoned as members of the group of ductless glands, which possess a somewhat different character. In them the elaboration of a chemical internal secretion is not the outstanding and characteristic function. The predominant activity of the spleen, for example, consists in the formation and the destruction of organised structural units in the form of living blood cells. The activity of the thymus gland is likewise in large measure cytoblastic. It is true that there is a good deal of evidence to show that the thymus does exert an influence of a chemical nature upon the general bodily metabolism. But this may also be said of many other organs. The liver, pancreas, gastric and intestinal mucous membranes; the kidneys, testes, and prostate; the uterus and ovaries have all been recognised as sources of more or less active products which enter the general circulation and affect the metabolic balance of the body. But these organs are not on that account reckoned as ductless glands or endocrine organs, though it is not improbable that specific portions of some of them, like the islets of Langerhans in the pancreas and the interstitial cells of the testes and ovaries, are actually entitled to some such recognition.

From the point of view of both its structural and functional affinities the spleen ought to be grouped with other corpuscle-forming or hæmopoietic organs like the lymph and hæmolymph glands. The latter indeed appear to present a structure intermediate between splenic and lymph-glandular tissue.

A valid and perhaps a useful distinction might very well be drawn between organs whose sole or whose characteristic function is to elaborate internal secretions of a chemical nature, and those whose output of material is in the form of organised corpuscular structures.

It is the former group that constitutes the ductless glands *sensu stricto.*

Were this distinction generally recognised it would tend to exclude the

spleen—and possibly also the thymus, in spite of its ontogenetic affinity with the thyreoid apparatus — from the class of ductless glands. These organs will nevertheless be here included with the ductless glands proper in accordance with anatomical use and wont.[1]

Under the general heading of ductless glands we include, for descriptive purposes, in this section—

1. The suprarenal gland.
2. The various "paraganglia," including the "aortic bodies."
3. The glomus caroticum or glandula carotica.
4. The glomus coccygeum.
5. The thyreoid gland.
6. The parathyreoid glands.
7. The thymus gland.
8. The hypophysis cerebri (pituitary body or gland).
9. The pineal body.
10. The spleen.

In addition to these more definite and discrete masses, glandular endocrine tissue may be present in the substance of other organs. It is held by many that the so-called "islets of Langerhans" scattered throughout the pancreas, and the "interstitial cells" disseminated throughout the stroma of the testis and ovary, represent specific endocrine tissue. But inasmuch as these disseminated elements, even if genuinely endocrine in function, do not constitute anatomically defined organs or masses, they are not dealt with in the present connexion. There is also a good deal of evidence that the significance of the corpus luteum of the ovary may be summed up in its internal secretory activities. It may be looked upon as a cyclically-appearing ductless gland. Its appearance is described in connexion with the structure of the ovary.

The various members of this rather heterogeneous collection of organs differ amongst themselves in structural features, in physiological characters, and in developmental origin.

They may be divided up into several subordinate groups, although any such attempt at classification is complicated by the fact that several of them exhibit a duplex constitution owing to a dual origin from developmentally distinct primordia.

The following sub-groups may be recognised:—

(1) A chromaffin group, of ectodermal origin, including the medulla of the suprarenal gland and various "paraganglionic" masses.

(2) A cortical group, of mesodermal origin, represented by the cortex of the suprarenal gland and by the occasional "accessory cortical bodies" of similar character.

(3) A pharyngeal pouch group, of entodermal origin, which includes the thyreoid gland, the parathyreoid glands, and the thymus glands. With the thyreoid, in its embryonic condition, are associated also the ultimo-branchial bodies. These, however, soon disappear as such.

(4) A cerebro-glandular group of ectodermal origin, consisting of the pituitary hypophysis and the pineal body.

(5) A lymphoid group, of mesodermal origin.

This group might well be so extended as to become the practical equivalent of the B.N.A. group of "glandulæ vasculares." This includes the spleen, thymus, tonsils, lymph glands (including hæmolymph glands) and the lymphatic nodules or follicles. The group thus established offers, as already suggested, a significant contrast to the preceding, more distinctively endocrine, groups. But existing anatomical convention annexes the description of the lymph glands to the vascular system and that of other lymphatic follicular structures to the alimentary system. The thymus will be dealt with in the company of its developmental congeners,

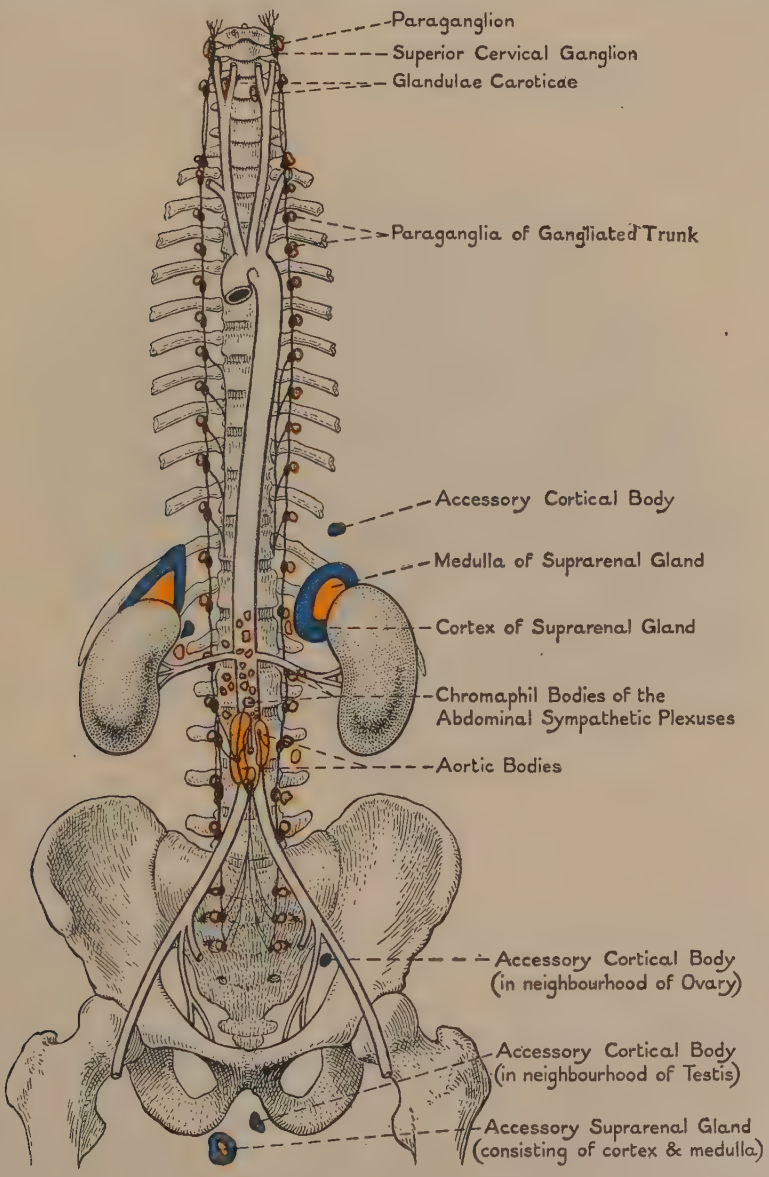
[1] The category of "glandulæ clausæ" of the B.N.A. terminology is obviously the nominal equivalent of the "ductless glands." But the B.N.A. usage excludes from that category the entire group of "glandulæ vasculares" which embraces the spleen, thymus, and tonsil as well as the lymph glands and lymphatic nodules.

the thyreoid and parathyreoid glands. The spleen, therefore, alone remains to represent in this chapter the lymphoid group of the ductless glands.

1. THE CHROMAFFIN GROUP.

(Synonyms: *Chromaphil, Phæochrome, System.*)

This group consists of a number of masses of glandular tissue containing cells which produce the substance known as adrenin. The tissue is called chromaffin,



Paraganglion
Superior Cervical Ganglion
Glandulae Caroticae
Paraganglia of Gangliated Trunk
Accessory Cortical Body
Medulla of Suprarenal Gland
Cortex of Suprarenal Gland
Chromaphil Bodies of the Abdominal Sympathetic Plexuses
Aortic Bodies
Accessory Cortical Body (in neighbourhood of Ovary)
Accessory Cortical Body (in neighbourhood of Testis)
Accessory Suprarenal Gland (consisting of cortex & medulla)

Fig. 1025.—Diagram of the Chromaffin and Cortical Systems. Modified from Swale Vincent
Chromaffin tissues = yellow ; cortical tissue = blue.

or chromaphil, tissue, on account of its affinity for chromium salts which give a brown or yellow reaction with the specific granular content of the cells. The general distribution of the masses of tissue forming the system is shown in Fig. 1025. They all originate in intimate association with the primordia of the

sympathetic nervous system. Indeed, the characteristic chromaffin cells and the cells of the sympathetic ganglia are both alike derivatives from a common mother type of cell.

The chromaffin group includes (i.) paraganglia associated with the "vertebral" or "lateral" ganglia of the sympathetic trunk; (ii.) paraganglia associated with the sympathetic plexuses, more especially in the abdominal region: these are doubtless cell masses having a common origin with the "prevertebral" or "collateral" ganglia of these plexuses; (iii.) the glandulæ caroticæ (B.N.A. glomera carotica) which are probably likewise paraganglionic in origin; (iv.) possibly, though more doubtfully, the glomus coccygeum: this body, though said to contain no actual chromaffin tissue, appears nevertheless to be connected in development with the sympathetic; and (v.) the medullary portions of the suprarenal glands.

(i.) The **paraganglia** associated with the ganglia of the sympathetic trunk are rounded masses of chromaffin tissue, 1-3 mm. in diameter, placed inside, half inside, or immediately outside the capsules of the ganglia. Typically one paraganglion, but occasionally more than one, is associated with each ganglion. They correspond to the "suprarenal bodies" of the Selachia.

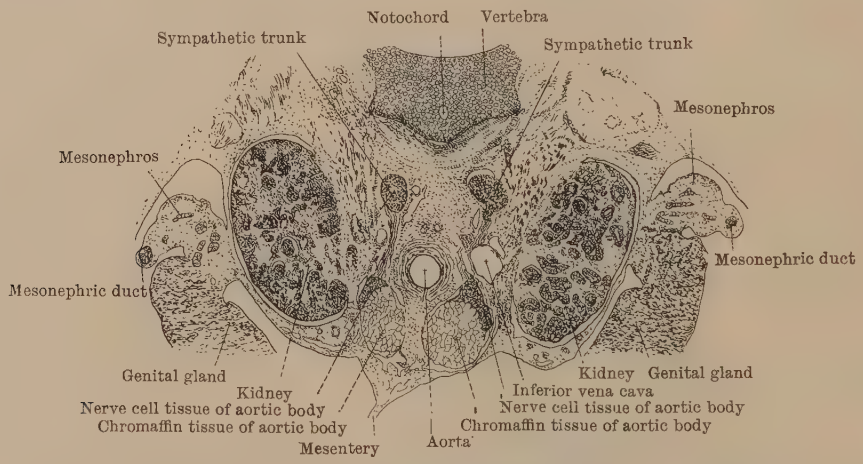


FIG. 1026.—TRANSVERSE SECTION OF PART OF THE ABDOMINAL REGION OF A 25-MM. HUMAN EMBRYO. Seen from below, showing aortic bodies.

(ii.) The **paraganglia** of the sympathetic plexuses occur both in association with the "collateral" ganglia and scattered throughout the plexuses. They may be very numerous—up to as many as seventy have been counted—though the number is usually much smaller. Increase in the number may be due to subdivision of masses.

They are also found in relation to viscera, where they doubtless originate in common with "terminal" or "peripheral" sympathetic ganglionic groups. The viscera to which they have been found related include the kidney with its pelvis and ureter, the suprarenal gland, the prostate, the paroöphoron and ovary, and the epididymis. The most important paraganglia or chromaphil bodies of the sympathetic plexuses are the two *aortic bodies* which lie ventral to the aorta in the region of the origin of the inferior mesenteric artery (Fig. 1026). In the new-born child they are smooth brownish structures, elongated in the cranio-caudal direction, and about a centimetre in length. Their form and arrangement are, however, subject to considerable variation, and they are often united medially by an isthmus. They undergo regressive change as life advances, ceasing to be visible soon after puberty though recognisable microscopically until middle life. In the vicinity of the aortic bodies there are usually numerous small masses of like character and of varying size and shape. Fig. 1026 illustrates the appearance of the aortic bodies as seen in a transverse section through the abdominal region of a human embryo of 25 mm. The relations of the aortic bodies to the aorta, the kidneys, the

sympathetic nerve plexuses, and the root of the mesentery are evident. The darker stippled areas along the periphery of the bodies represent developing sympathetic ganglia of the abdominal plexus.

(iii.) The **glandula carotica** (B.N.A. **glomus caroticum**; O.T. **intercarotid body**) is a bilateral paired organ situated in close but slightly variable relation to the bifurcation of the common carotid artery. It is associated with the carotid, or intercarotid, nerve plexus. There is often a localised thickening of the adjacent arterial wall. Frequently it lies deep to the bifurcation; sometimes it is wedged in between the internal and external carotids at their commencement; sometimes it is placed between them at a slightly higher level. Its shape varies with its position. When free from pressure it is oval; when compressed by the internal and external carotids it is wedge-shaped. On the average, its height is 7 mm., its breadth 1·5-5 mm. Not infrequently it is split into two or more nodules. Its colour is grayish, yellowish, or brownish red.

FIG. 1027.—SECTION THROUGH GLOMUS COCCYGEUM (highly magnified). (From J. W. Thomson Walker.)

Structure.—The glandula carotica is built up of nodules of chromaffin tissue surrounded and supported by fibrous tissue. The nodules are penetrated by a mass of sinus-like blood capillaries and surrounded by large lymph vessels. Scattered nerve-cells are present, and the whole organ is permeated by non-medullated nerve-fibres, which establish intimate connexion with the chromaffin cells.

(iv.) The nature and affinities of the glomus coccygeum are still uncertain. In spite of its apparently complete lack of chromaffin cells, its general histological resemblance to the carotid gland and its probable association with the sympathetic in development may be held to justify its description in this connexion.

The **glomus coccygeum** is a small vascular body from 2-3 mm. in diameter. It lies immediately anterior to the tip of the coccyx in intimate relation to a branch of the middle sacral artery. Usually its main mass is accompanied by a group of smaller bodies of similar structure and arterial relationship.

Structure.—This usually composite glomus is enclosed in a fibrous capsule giving sheaths both to the chief mass and the satellite bodies. The characteristic structure of the glomus consists of masses of polyhedral cells with large nuclei, surrounding the lumina of a tortuous arrangement of sinusoidal blood spaces (Fig. 1027). From these spaces capillary channels extend

among the investing masses of closely packed cells. Apparently none of these cells show the characteristic chromaffin reaction (Stoerk and Zuckerkandl).

Development of the Chromaphil System and of the Glomus Coccygeum.—All chromaffin tissue develops in intimate relation with the sympathetic nervous system. It is not derived from the sympathetic tissue nor is the sympathetic tissue derived from it. Both are the descendants of a primitive, indifferent, sympatho-chromaffin blastema, which in a 16-mm. embryo occupies the regions corresponding to those occupied by the sympathetic system of the adult. It is composed of tightly-packed deeply-staining cells about 5 μ in diameter. The ancestry of these cells can be traced back with strong probability to cells which migrate from the neural crest, or from the wall of the medullary tube, or from both of these regions (see Development of the Sympathetic Nervous System).

The differentiation of chromaphiloblasts from sympathoblasts begins when the embryo is about 18 mm. in length, but is not completed until late in gestation, if then. The process is marked by an increase in size of the chromaffin formative cells and by a diminution in the intensity of their reaction to ordinary stains. Later, the specific chrome reaction develops, but the exact stage at which this occurs is unknown. It is important to note that if any cells in an area differentiate, all do. The result is that, in spite of their intimate relations and common origin, an intermixture of chromaffin and sympathetic cells is extremely rare.

The first of the chromaffin masses to differentiate are the aortic bodies. They are prominent structures in the two-months embryo (*vide* Fig. 1026). Later, the paraganglia of the sympathetic plexuses develop, and last the paraganglia of the gangliated trunk.

The development of the glandula carotica requires special description. It takes origin from a strand of sympatho-chromaffin blastema, which extends ventrally from the region of the superior cervical sympathetic ganglion, deep to the internal carotid artery or between the internal and external carotids. Differentiation begins when the embryo is about 20 mm. in length, and is completed by the time it is 30 mm. long. In connexion with the development of the glandula, there is a peculiar thickening of the wall of the internal carotid artery near the developing gland. In the dog a similar thickening of the wall of the internal carotid artery takes place, although in that animal the glandula lies beside the external carotid. Further, in a 45-mm. fœtus in which the glandula is fully differentiated the thickening is still present. These facts show that in the higher animals the thickening has no connexion with the development of the glandula, though the association of chromaffin bodies with blood-vessels in cyclostomata and elasmobranchs (see Comparative Anatomy of the Chromaffin and Cortical Systems) compels caution in excluding the possibility of there being at least some phylogenetic relation between the two. It has frequently been stated, and is widely held, that the glandula carotica is developed from, or receives some contribution from, the entoderm of the third pharyngeal pouch. This is not the case (see Parathyreoid Glands, Development).

Development of the Glomus Coccygeum.—The earliest stages of development of the glomus are still obscure. Its presence has not been recognised with certainty before the end of the fourth month of fœtal life. Jakobssohn claimed to show its developmental connexion with the sympathetic. This relationship has been rejected as unproved by Stoerk and by V. Schumacher, but their negative arguments are just as unconvincing as Jakobssohn's affirmative statements, inasmuch as they both deal with a stage in which evidence of an original genetic relation might well have disappeared. In any case it cannot be denied that there remains a fairly intimate topographical relationship of the gland with the caudal end of the sympathetic. If, however, the glandular-looking tissue of the glomus does actually originate from sympatho-chromaffin tissue, it seems certain that the chromaffin character is suppressed at an early period.

The alternative view, adopted by Stoerk and V. Schumacher, that the characteristic cells of the glomus are derived from the cells of the tunica media of the branches of the A. sacralis media, is difficult to accept. It may be noted in this connexion that a peculiar reaction of the wall of the carotid artery in relation to the glomus caroticum is noticeable during development, and has by some been erroneously regarded as genetically related to the formation of that organ, now admitted to belong to the chromaffin group by origin as well as by tissue reaction.

(v.) The **medullary** constituent of the suprarenal gland is the most important representative of the chromaffin system.

It is discussed below (p. 1329).

2. THE CORTICAL GROUP.

The single constant representative of this system in higher vertebrates is the mass of tissue forming the **cortex of the suprarenal gland.** Masses of similar tissue, however, are not infrequently met with in various situations, forming **accessory cortical bodies.**

The cortical tissue is peculiarly rich in lipoids, but its function is as yet undetermined. The positions in the human body which may be occupied by accessory cortical masses are indicated in Fig. 1025. They may be associated with chromaffin medullary tissue, as is the case in the suprarenal itself, but the majority, including the smaller bodies, are purely cortical. The justification for regarding

the suprarenal cortex, with the occasional accessory cortical masses, as representing a distinct system, is based upon both phylogenetic and ontogenetic considerations. These warrant the conception of an originally more extensive distribution of cortical tissue, distinct from, but more or less co-extensive with, the chromaffin system. In the higher vertebrates the cortical system would appear to have undergone concentration, and has thus come to be represented mainly by the cortex of the suprarenal gland (*vide infra* on Comparative Anatomy of the Chromaffin and Cortical Systems, p. 1330).

Glandulæ Suprarenales.

The **suprarenal glands** (O.T. **suprarenal bodies** or **capsules, adrenal glands**) are composite products of the chromaffin and cortical systems. Each consists of a relatively thick cortex enclosing a medulla of chromaffin tissue. Typically, there are two suprarenal glands, a right and left, placed in the epigastric region, one on each side of the vertebral column. They lie in the same plane as, and in intimate

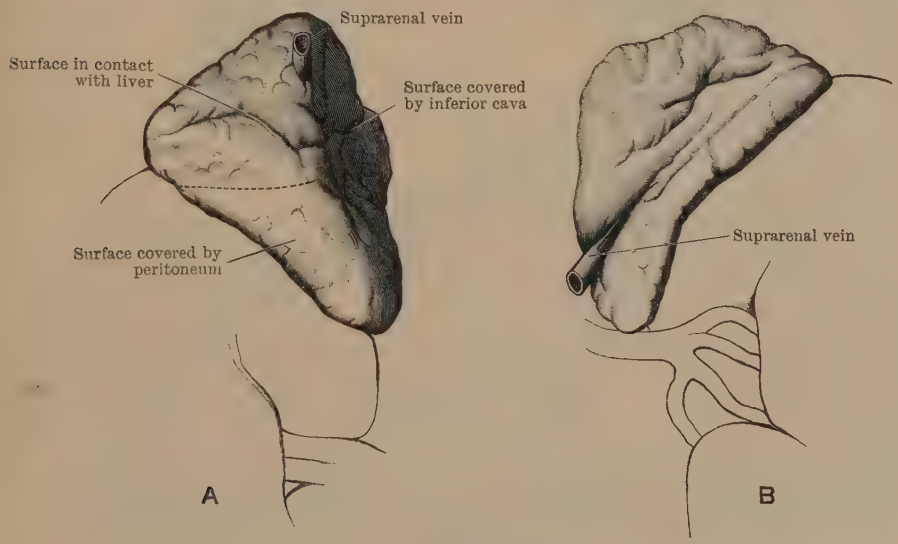

Fig. 1028.

A. Anterior surface of right suprarenal gland. B. Anterior surface of left suprarenal gland. The superior and medial parts of each kidney are indicated in outline. On the right gland the dotted line indicates the superior limit of the peritoneal covering.

relation to, the supero-medial aspects of the kidneys. Their colour is yellowish brown; their size varies within wide limits. To some extent it depends upon the cause of death. Average dimensions are: height, 5 cm.; breadth, 3 cm.; thickness, slightly under 1 cm.; weight about 7 gm. They are very little smaller at birth than in the adult.

Rarely only one gland is present; occasionally one is quite small, the other unusually large; as a rule they are unequal in size, the left being more frequently the larger. Sometimes the two glands are fused (cf. horse-shoe kidney). Frequently there are accessory glands. These develop in the neighbourhood of the main gland, and usually remain there, but may become attached, early in embryonic life, to organs which subsequently change their position. As a result, they may be found not only beside the main gland but also in the ligamentum latum uteri, on the spermatic funiculus, or even attached to the epididymis. Like the main glands, accessory suprarenals are compounded of cortex and medulla, and require to be distinguished from chromaffin bodies and accessory cortical bodies, which may be found in any of the positions in which accessory suprarenal glands occur.

Forms and Relations.—The suprarenal glands possess fairly constant forms and relations. The right gland is flat and triangular in outline. It is moulded, antero-laterally by the liver; antero-medially by the vena cava inferior; postero-medially by the diaphragm

above, and by the kidney below. In a formalin-hardened specimen these areas are separated by prominent ridges. Near the apex of the gland, within the area of contact with the vena cava inferior, there is a short fissure, the *hilum*. From this emerges a vein which immediately joins the vena cava. The left gland is also flat, but is semilunar in outline. It is moulded antero-laterally, by the stomach above, and by the pancreas below; postero-medially by the diaphragm above, and by the kidney below. Upon the anterior surface, near its lower end, is a well-marked fissure, the *hilum*. From this emerges a vein which almost immediately joins the left renal vein.

The relations of the right and left glands to the kidneys are different. The right lies like a cap upon the superior pole of the right kidney; the left is in contact with the

antero-medial border of the left kidney from the hilum to the superior pole. The relation of the glands to the peritoneum is not only different but variable. On the right side the peritoneum may cover the lower part of the antero-lateral surface of the gland; or this part may be in contact with the duodenum, in which case a small area about the middle of the surface may be covered by peritoneum; or the peritoneum may not come into relation with the gland at all. On the left side the upper part of the anterior surface is commonly covered by the peritoneum of the omental bursa, the lower part being crossed by the pancreas and splenic vessels. Sometimes these structures lie at a

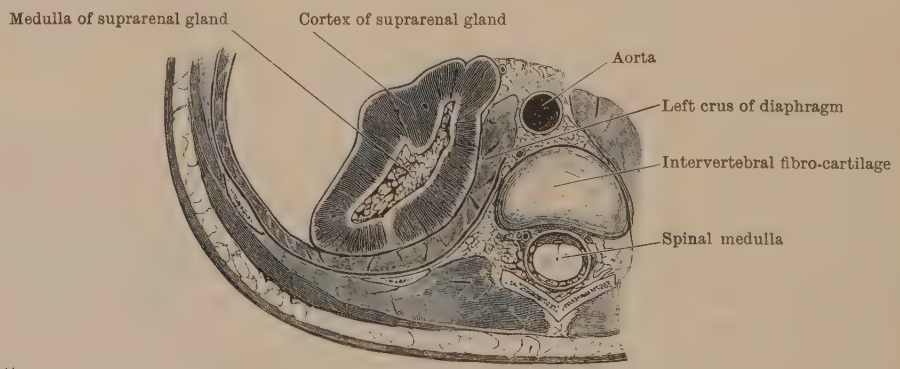

FIG. 1030.—TRANSVERSE SECTION THROUGH THE SUPRARENAL GLAND OF A NEW-BORN CHILD *IN SITU*.

lower level, when the whole antero-lateral surface is covered by peritoneum of the omental bursa.

Blood and Lymph Vessels.—The blood supply of the suprarenal is stated to be more abundant than that of any other organ in the body. Typically, each gland receives three arteries: one direct from the aorta, one from the inferior phrenic, and one from the renal artery; and is drained by one vein, which emerges at the hilum, the right to join the vena cava inferior, the left to join the left renal vein. Numerous lymph vessels pass from the suprarenal glands to the lateral aortic lymph glands.

Nerves.—The very numerous nerves passing to and from the glands constitute the suprarenal plexuses. They connect with the renal and cœliac plexuses and with the cœliac ganglia, and include numerous direct fibres from the greater splanchnic nerves, with a smaller number from the vagus and phrenic nerves. Most of them are medullated, but lose their sheaths on passing

into small ganglia in, or just within, the fibrous capsule of the gland. Thereafter they pass to the chromaffin tissue of the medulla, either directly, or after first supplying the cortex.

Structure.—A suprarenal gland consists of a highly vascular central mass of chromaffin tissue, the *medulla*, enclosed within a thick capsule of cortical substance, the *cortex*, which in turn is enclosed within a capsule of fibrous tissue, *tunica fibrosa*. From the deep aspect of the fibrous tunic trabeculæ pass inwards to support the glandular tissue. In the superficial part of the cortex the trabeculæ interlace freely to enclose rounded loculi, *zona glomerulosa* (Fig. 1031, 1); in the intermediate part they run vertically to the surface to enclose columnar spaces, *zona fasciculata* (Fig. 1031, 2); in the deepest part of the cortex they become broken up and form a reticulum, *zona reticulata* (Fig. 1031, 3).

The cortex consists of polyhedral cells arranged in the interstices of the fibrous trabeculæ. These cells contain a lipoid substance, which is present in sufficient quantity to give the cortex a yellow colour.

The medulla (Fig. 1031, 4) is formed of a spongework of cell columns bounding anastomosing venous sinusoids. The cells are large, contain numerous granules, and possess the specific chromaffin reaction. In a fresh gland the medulla is of a dark red colour owing to the presence of blood in its sinusoidal circulation.

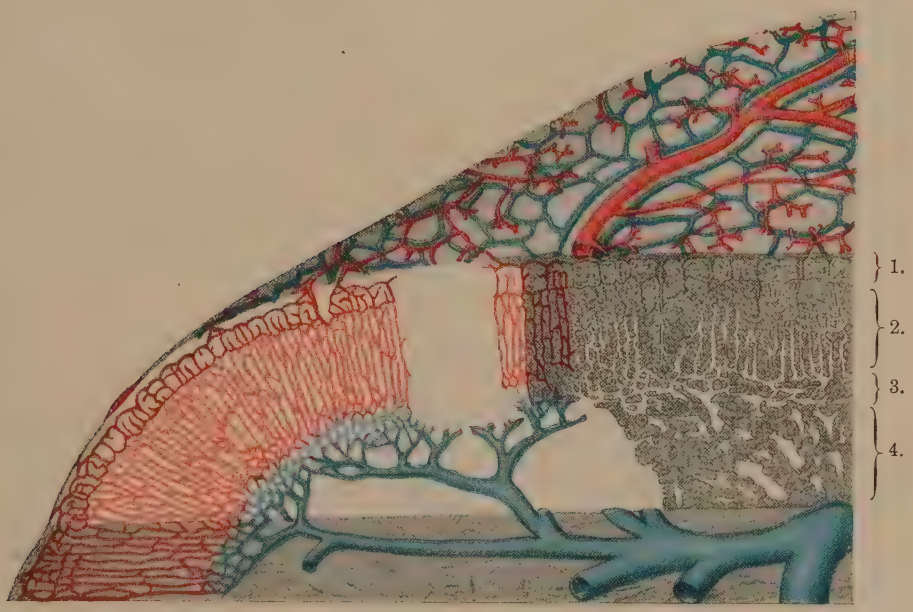

Fig. 1031.—Reconstruction of Suprarenal Gland of a Dog. (From Marshall Flint.)

The upper part shows the arrangement of blood-vessels upon the surface of the gland, the lower part their arrangement within its substance.

1. = Zona glomerulosa corticis.
2. = Zona fasciculata corticis.
3. = Zona reticulata corticis.
4. = Medulla.

The blood-vessels enter at numerous points in the fibrous capsule and run in the trabeculæ, forming a capillary network around the cell masses and columns of the zona glomerulosa and zona fasciculata. In the zona reticulata the blood-vessels open up to form a venous plexus, which is continuous with the sinusoidal plexus in the medulla, and thus mediately as well as more directly with the central efferent vein of the medulla which emerges at the hilus of the organ as the suprarenal vein.

Development of the Cortical System and of the Suprarenal Glands.—The cortical system is a derivative of the cœlomic epithelium (mesoderm). The first indication of its development is given, when the embryo is about 6 mm. in length, by the rapid proliferation of the epithelial cells placed between the mesonephros and the root of the mesentery. Numerous buds form and penetrate the mesenchyme at the sides of and ventral to the aorta. In an 8-mm. embryo these buds have already lost their connexion with the cœlomic epithelium. By the time the embryo is 9 mm. long the developing cortical masses are becoming vascularised. In man the greater part of the tissue thus formed is ultimately included in the cortex of the suprarenal glands, but small masses may escape, either at this stage or subsequently, to form independent cortical bodies.

In 12-mm. embryos the developing suprarenal glands lie in a caudalward continuation of the dorsal portion of the pleuro-peritoneal membrane called the suprarenal ridge, now distinctly marked off, and are composed of cortical tissue only. When the embryo is about 20 mm. in length sympatho-chromaffin cells, destined to form the medulla of the gland, begin to migrate into the developing cortex. The two kinds of tissue are in contact in 10-12 mm. embryos, but

penetration of cortical masses by sympatho-chromaffin cells has not been observed earlier than the stage mentioned.

At first the immigrating cells are scattered in numerous columns and strands, and it is not until the embryo is about 10 cm. in length that they begin to reach the central vein and to form a true medulla. When the process of immigration ceases is unknown, probably not until after birth.

The final specialisation of the cortex is a late phenomenon, and does not take place until long after birth. The zona reticulata develops early and is recognisable in a 15-mm. embryo; the zona glomerulosa is not formed until the second or third year, but is represented until then by a layer of small incompletely specialised cells immediately under the fibrous capsule.

During fœtal life the cortex is relatively enormous. This is due to a great proliferation of the cells of the fœtal zona reticulata, which differ from the adult cells of the same zone in not containing lipoids. This fœtal cortex begins to undergo a fatty degeneration soon after birth, and by the end of the first year has disappeared. The new cortex which replaces it develops from the small, superficially placed, incompletely specialised cells already referred to.

Comparative Anatomy of the Chromaffin and Cortical Systems.—A knowledge of the main facts of the comparative anatomy of the chromaffin system is a help to understanding its distribution in man. Chromaffin tissue is first recognised with certainty in the cyclostomata, in which it is arranged in thin strips on the walls of the larger arteries and their branches. In elasmobranchs chromaffin bodies are present (the so-called "suprarenals" of this group of animals), and are arranged segmentally on branches of the aorta in close relation to the ganglia of the sympathetic chain. Cortical tissue is also recognisable in the cyclostomata, in which it is arranged in small lobulated masses (the "interrenal corpuscles"), in the walls of the posterior cardinal veins, and renal arteries. Even in this rudimentary form it is rich in lipoids. In the rays (elasmobranchs) the cortical system is represented by a pair of yellow-coloured, rod-shaped interrenal structures in the region of the kidney. In batrachians the chromaffin and cortical representatives first begin to come together. In the frog the adrenals are golden yellow streaks on the ventral surface of the kidney. The greater part of these are made up of columns of cortical cells, but at the borders or ends of the cell columns masses of chromaffin cells occur. This arrangement is transitional between the complete independence of the chromaffin and cortical systems in elasmobranchs and the partial inclusion of chromaffin tissue within cortical characteristic of the higher mammals (Swale Vincent).

3. THE PHARYNGEAL GROUP.

A third subdivision of the ductless glandular organs includes those which are derived developmentally from the entodermal pouches of the embryonic pharynx. They are (i.) the thyreoid gland, (ii.) the parathyreoid glands, (iii.) the thymus glands.

The embryonic primordia from which these organs are formed are rather numerous and include, in addition to those so named, (iv.) the ultimo-branchial bodies which early disappear, either completely or as distinct and separate structures.

(i.) Glandula Thyreoidea.

The **thyreoid gland** (O.T. **thyroid body**) is placed in the neck, firmly bound by fibrous tissue to the anterior and lateral aspects of the upper part of the trachea and to the sides of the larynx. It is yellowish red, soft, and vascular. It varies in size with age, sex, and general nutrition, being relatively large in youth, in females, and in the well-nourished. In women it increases temporarily with menstruation and pregnancy. Its average dimensions are, height 5 cm., breadth 6 cm., thickness of lateral lobes 1-2 cm., weight 25 gm.; but these measurements are of little value because of the range of variation.

Conventionally, the thyreoid gland is said to consist of two conical, more correctly pyramidal, lateral **lobes** united across the middle line by a narrow band of gland tissue, the **isthmus.** To many thyreoids this description is inapplicable. In men and thin elderly spinsters the gland is not uncommonly horse-shoe shaped; in young well-nourished women and in pregnancy its general contour suggests a sphere, deeply notched superiorly to accommodate the larynx and deeply grooved posteriorly for the trachea and œsophagus. Rarely, the gland is in two separate parts. Not infrequently, it is asymmetrical. In about 40 per cent. of specimens a process of gland tissue, the **pyramidal lobe,** extends from the upper border of the isthmus, upwards, in front of the cricoid and thyreoid cartilages, towards the hyoid bone. This process is seldom median, lying more often on the left than on the right. In rare cases, it is double. Less rarely, it is double below and single above. Sometimes it is represented by a strip of fibrous tissue or a

narrow muscle (lig. suspensorium, or m. levator glandulæ thyreoideæ). The muscle may, however, be present independently of the pyramidal lobe.

Small oval accessory thyreoid glands are common in the region of the hyoid bone, and are occasionally met with in relation to the right and left lobes.

The relations of the gland are variable, depending upon its size and its relative level. In a majority of cases the isthmus covers the second, third, and fourth rings of the trachea, but it may cover the cricoid cartilage, or the fourth, fifth, and sixth tracheal rings. Anteriorly, the gland is clothed by the pretracheal lamina of cervical fascia, which separates it from the sterno-thyreoid, sterno-hyoid, and omo-hyoid muscles. Fibro-areolar extensions of this fascial layer form an indefinite capsule for the gland. Of these extensions one median and two lateral constitute ligaments binding the gland to the cricoid and thyreoid cartilages and to the upper cartilaginous rings of the trachea. Postero-medially, the thyreoid gland is moulded by the sides of the trachea and lower part of the larynx, and, when large, comes into contact, behind them, with the pharynx and œsophagus. Postero-laterally, it is in relation to the common carotid arteries, and when large is in intimate relation to the recurrent nerves. Further, it has important relations to the parathyreoid glands (see Parathyreoid Glands, Relations).

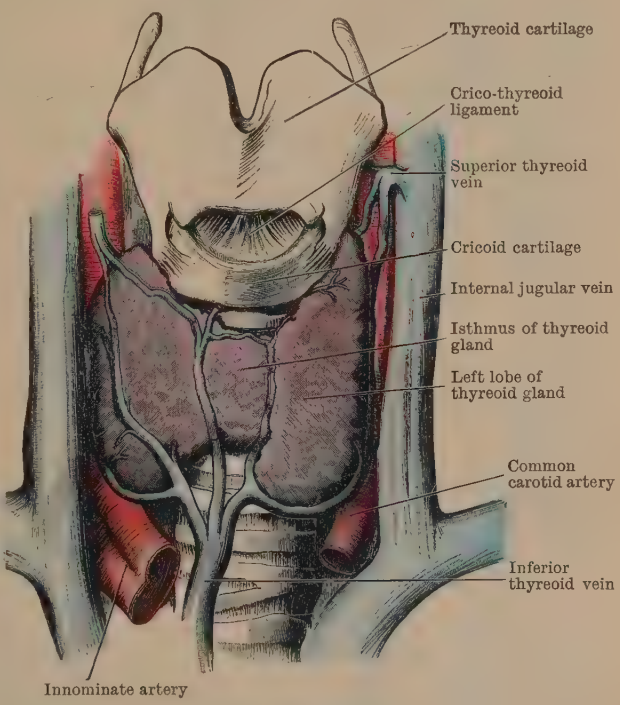

FIG. 1032.—DISSECTION OF THE THYREOID GLAND AND OF THE PARTS IN IMMEDIATE RELATION TO IT.

Blood and Lymph Vessels.—The extraordinarily rich blood supply is effected through the superior thyreoid arteries, branches of the external carotids, and through the inferior thyreoid arteries, branches of the thyreo-cervical trunks. Occasionally (10 per cent of cases) a fifth artery is present, the thyreoidea ima, usually a branch of the innominate. The pyramidal lobe, if well developed, receives a special branch from one of the superior thyreoids, usually the left. These arteries are remarkable for their large size and for the frequence and freedom of their anastomoses. An anastomosing trunk courses up the posterior aspect of each lateral lobe, uniting the inferior and superior thyreoid arteries. It is of interest in connexion with the recognition of the parathyreoid glands. Typically, three pairs of veins drain the gland. The upper two pairs, the superior and middle thyreoid veins, join the internal jugulars; the lower pair, the inferior thyreoid veins, join the left innominate. These vessels take origin from a venous plexus on the surface of the gland or, in the case of the inferior, from a downward extension of the plexus in front of the trachea. When the gland is very large, accessory veins are present, sometimes in considerable numbers. Most of these pass to the internal jugulars. A free, transverse, venous anastomosis is effected along the borders of the isthmus through the superior and inferior communicating veins.

The lymph vessels anastomose freely in the substance and on the surface of the gland. Most pass direct to the deep cervical lymph glands, a few descend in front of the trachea to the pretracheal lymph glands.

Nerves.—The nerves are non-medullated and are derived from the cervical sympathetic. They accompany the blood-vessels forming superior and inferior thyreoid nerve plexuses ending on the walls both of the blood-vessels of the gland and of the gland follicles.

Structure.—The gland is enclosed in a fibrous capsule (tunica propria) which sends prolongations inward to form a framework for the gland tissue proper. This consists of irregular lobar subdivisions made up of lobular groups of spheroidal vesicles or follicles, ·04 mm. to 1 mm. in diameter, lined with cubical epithelium, and filled with "colloid." The size, shape, and cellular characters of the vesicles vary with diet and environment. The vesicular follicles are surrounded by networks of blood capillaries and of lymph vessels.

Development.—The thyreoid gland takes origin from a single median outgrowth from the pharyngeal floor (entoderm). It is recognisable as a shallow bay in a 1·8-mm. embryo,

practically simultaneously with the demarcation of the foregut. As the bud grows its end expands whilst its stalk narrows to form the *thyreo-glossal duct.*

In a 4-mm. embryo an elevation is present round the pharyngeal opening of the duct. This is the tuberculum impar. It migrates forwards, the duct backwards, so that in a 5-mm. embryo the duct opens into the furrow immediately caudal to the tuberculum (see Tongue, Development). At about this stage obliteration of the duct begins. This process proceeds slowly and is seldom quite complete, a vestige of the duct, *the foramen cæcum of the tongue*, remaining in the adult.

While these processes are proceeding growth and lateral expansion of the bud continue. It becomes bilobed and has a divided lumen, and all the while it undergoes a continuous relative displacement caudalwards. During this period it usually loses entirely its connexion with the pharyngeal wall and its lumen disappears. In a 9-mm. embryo the developing thyreoid gland is a transverse bar composed of irregular anastomosing cell columns.

In the meshes of this formation is vascular mesenchyme.

In embryos of 24 mm. (Norris) lumina appear amid the cells of the epithelial cords which have become clumped into groups. The "primary follicles" thus arising give origin to "secondary follicles" by processes of budding and constriction. This formation of secondary follicles begins at about the tenth week (55-mm. embryo) and is most active up to the stage of 160 mm.

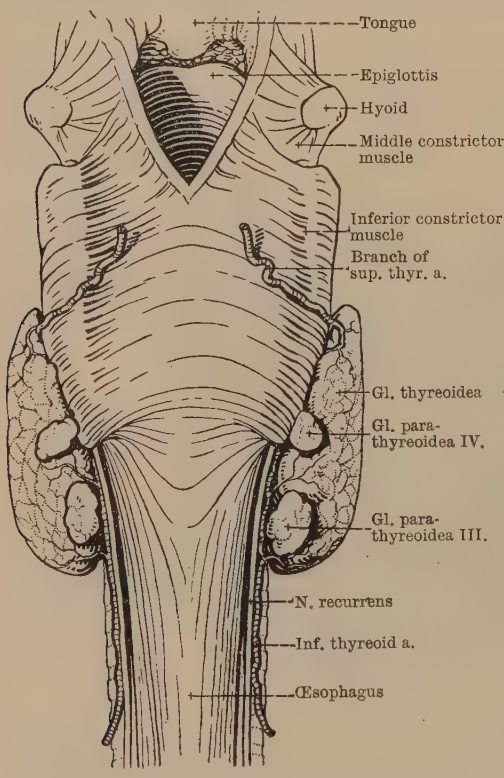

FIG. 1033.—DISSECTION SHOWING THYREOID AND PARATHYREOIDS OF ADULT FROM BEHIND.

In the pig, colloid first appears in the secondary follicles in 75-mm. embryos.

In the later period of fœtal life the glandular growth is probably mainly due to increase in size rather than in number of the follicles.

It is usually stated that, contrary to older views, no permanent contribution to the definite thyreoid is made from any of the lateral pharyngeal pouches. But it is generally admitted that a pharyngeal pouch element—the so-called ultimo-branchial body—becomes temporarily incorporated with the lateral portions of the median thyreoid rudiment. Badertscher (1918–1919) has recently shown that, in the pig, true thyreoid follicles, which develop colloid in their interior, do arise from the material of the ultimo-branchial bodies, embedded in the lateral regions of the thyreoid. A similar view has also been expressed for marsupials. If this interpretation be confirmed the older idea of the composite origin of the thyreoid from median and lateral primordia would be rehabilitated. It is possible, however, that the fate of the ultimo-branchial bodies is a variable one, as Stewart (1918) has recently surmised.

The developmental history of the gland affords a ready explanation of its variations in the adult. Thus the development of a pyramidal lobe and its variations, partial and complete duplication, are due to the development of gland tissue from that part of the thyreo-glossal duct which has a double lumen and the more or less complete fusion or separation of the masses thus formed. Accessory thyreoid glands near the hyoid bone are the result of a similar process in connexion with isolated remnants of the duct.

The occurrence in the adult of a duct leading from the foramen cæcum to, or towards, the hyoid bone (*lingual duct*) is due to a persistence of the upper part of the thyreo-glossal duct. Similarly, *thyreo-glossal cysts* are due to the persistence of short intermediate lengths of the duct.

(ii.) GLANDULÆ PARATHYREOIDEÆ.

The **parathyreoid glands** (O.T. **parathyroid bodies**; *Synonyms*: epithelial bodies, parathymi or parathymic glands, "glandules thymiques" or "glandules thyreoïdiennes" of some French authors) are finely granular, yellowish brown, lenticular, or ovoid structures, from 2 to 20 mm. in diameter and from ·01 to 3 gm. in weight. Most commonly they are lenticular, 5-7 mm. in length, 1-2 mm. in thickness, and from ·01 to ·1 gm. in weight. Normally there are two pairs of parathyreoids, distinguished by the Roman numerals IV. and III. to signify that they

develop from the fourth and third pharyngeal pouches. The normal total number may be diminished to three, two, or even one. It may, on the other hand, be increased, since in course of development the parathyreoid buds may divide so that more than four, five to twelve, glands may be present: the numerals are then applied to the groups of glands formed from the pouches.

Parathyreoid IV. is commonly embedded in the tunica propria of the thyreoid gland and lies posterior to the corresponding lateral lobe of that organ, about its middle. Parathyreoid III., similarly embedded, usually lies on the posterior aspect of the inferior extremity of the lateral lobe of the thyreoid gland. As a rule the anastomosing channel, which connects the inferior and superior thyreoid arteries (see Thyreoid Gland, Blood Supply), passes near both parathyreoids and furnishes the best guide to their discovery, but the range of the exceptional positions which the glands may occupy is wide. Thus, parathyreoid IV. may be found (1) behind the pharynx or œsophagus, (2) in the fibrous tissue at the side of the larynx, above the level of the thyreoid gland, (3) behind any part of the corresponding lobe of the thyreoid gland or even embedded in the thyreoid substance (internal parathyreoid); whereas parathyreoid III. may be found (1) near the bifurcation of the common carotid artery, (2) behind any part of the corresponding lobe of the thyreoid gland, (3) on the sides of the trachea, or (4) in the thorax close to the thymus. This wide range of variation in position is explicable by the close association of parathyreoid III. with the main thymus element in development (*v. infra*).

FIG. 1034.—OBLIQUE SECTION THROUGH PART OF THE TRACHEA AND THE RIGHT LOBE OF THE THYREOID GLAND OF A HUMAN FŒTUS 60 MM. LONG. Showing the parathyreoid embedded in the capsule of the gland.

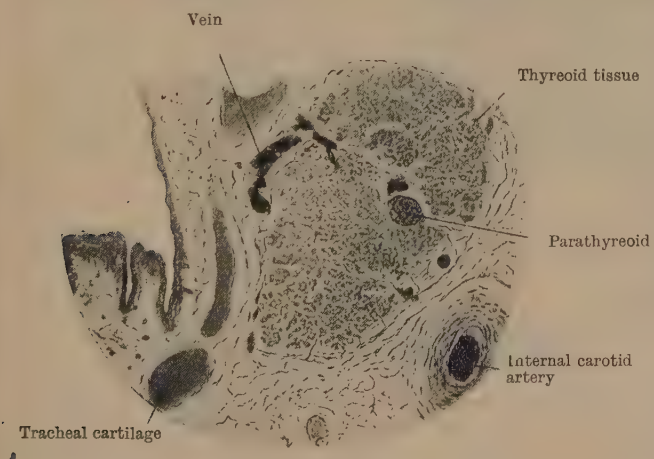

FIG. 1035.—OBLIQUE SECTION THROUGH PART OF THE TRACHEA AND THE LEFT LOBE OF THE THYREOID GLAND OF A HUMAN FŒTUS 60 MM. LONG. Showing the parathyreoid embedded in the thyreoid gland.

Blood-vessels.—The blood supply of each parathyreoid is effected by a single artery which enters the gland at its hilum. It may spring from any branch of the inferior or superior thyreoid arteries, but most commonly is a branch of the large anastomosing channel already referred to.

Structure.—The parathyreoids are built up of intercommunicating trabeculæ of epithelial cells with strands of vascular connective tissue between them. Sometimes the cellular arrangement is of a more compact character. The vascular network of the gland is sinusoidal. The cells are of two kinds, one clear, the other, the minority, containing oxyphil granules. Colloid-containing follicles are not infrequently found, though the colloid is said to differ from that of the thyreoid follicles in the absence of iodine. Thyreoidectomy seems to induce an increase in these colloid-containing follicles.

Development.—The parathyreoid bodies develop from the dorsal diverticula of the third and fourth pharyngeal pouches. The first indication of their development is a proliferation and

thickening of the epithelium on the cranial and lateral aspects of the diverticula. This is present in both the third and fourth pouches in 9-10 mm. embryos, but appears to be rather irregular in the time of its appearance. The cells forming it are vacuolated, difficult to stain, and indistinct in outline. Cords of cells grow out from the thickening, and fibrous tissue penetrates between the outgrowing cords, which soon lose their connexion with the pharynx. The differentiation of the two kinds of cells takes place after birth.

Parathyreoid III. is normally drawn by the thymus, as it migrates, caudal to parathyreoid IV. As a rule it halts at the level of the inferior extremity of the lateral lobe of the thyreoid gland, but may continue its descent into the thorax or may not descend at all. In the latter case it remains near the bifurcation of the common carotid artery, where it is apt to be confused with the glandula carotica. It is from this confusion that the idea, that the chromaffin glandula carotica arises from the third pharyngeal pouch, has obtained a foothold in anatomical teaching.

(iii.) Thymus.

Strictly, there are two thymus glands, a right and a left, but they are so intimately related that it is customary to speak of them as a single organ, the **thymus**. This body is placed usually entirely, and always for the most part, in the superior and anterior mediastina, although not uncommonly it extends into the lower part of the neck. Its size varies relatively and absolutely with age, sex, and nutrition. It is pre-eminently an organ of early life. It is already of considerable size at birth and continues to increase throughout childhood, reaching its acme of growth about puberty. After this period it undergoes gradual diminution from involution and fatty degeneration of its parenchymatous structure. On account of its variability it is impossible to say what should be the normal dimensions of the gland at the various ages. In some new-born babes it weighs as little as 2 or 3 gm., in others as much as 15-17 gm. At puberty it may be difficult to find, or may weigh as much as 40 gm. After the age of fifty it may require careful dissection to discover, or may be quite large. According to Hammar the thymus weighs on the average at birth about 13 gm., at puberty about 37 gm., at the end of the adolescent period about 25 gm., and in advanced age about 6 gm. Of these weights the proportion to be ascribed to the proper glandular tissue is much greater in early than in later life, being about two-thirds at puberty. The female thymus weighs 20 per cent less than the male. Conditions of malnutrition affect the size of the gland, and premature permanent

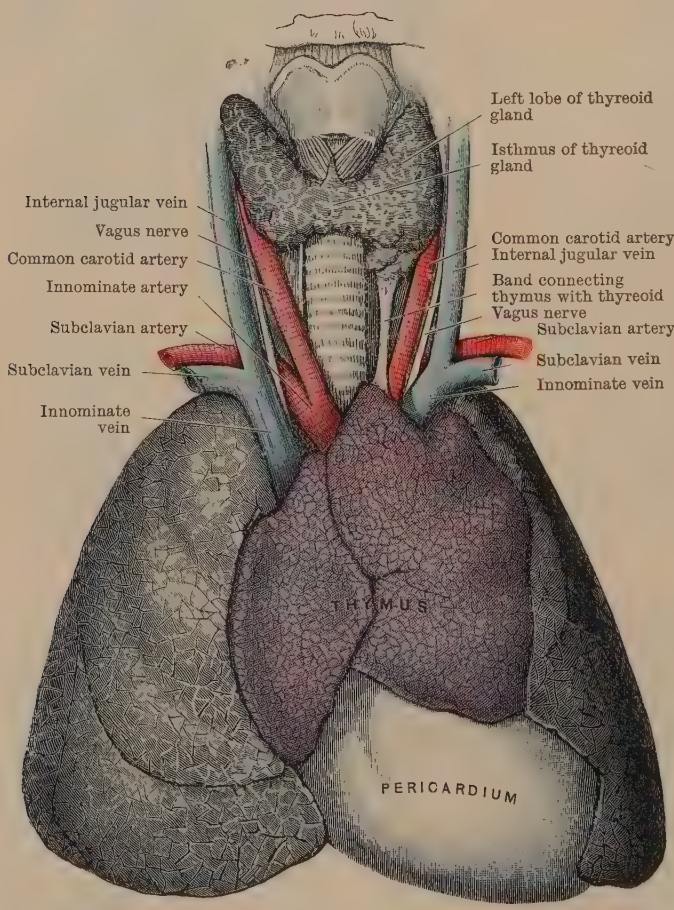

Fig. 1036.—Thymus and Thyreoid in a Full-time Fœtus hardened by Formalin-injection.

involution may result from severe illness, even though complete recovery may have taken place.

During the period of its fuller development the thymus appears as a pinkish mass (yellower in later life), consisting of two laterally compressed, more or less pyramidal, asymmetrical lobes. These are connected with one another, not by any bridge of glandular tissue but by areolar connective tissue.

The surface of the gland, in the young, more actively glandular, condition is finely lobulated.

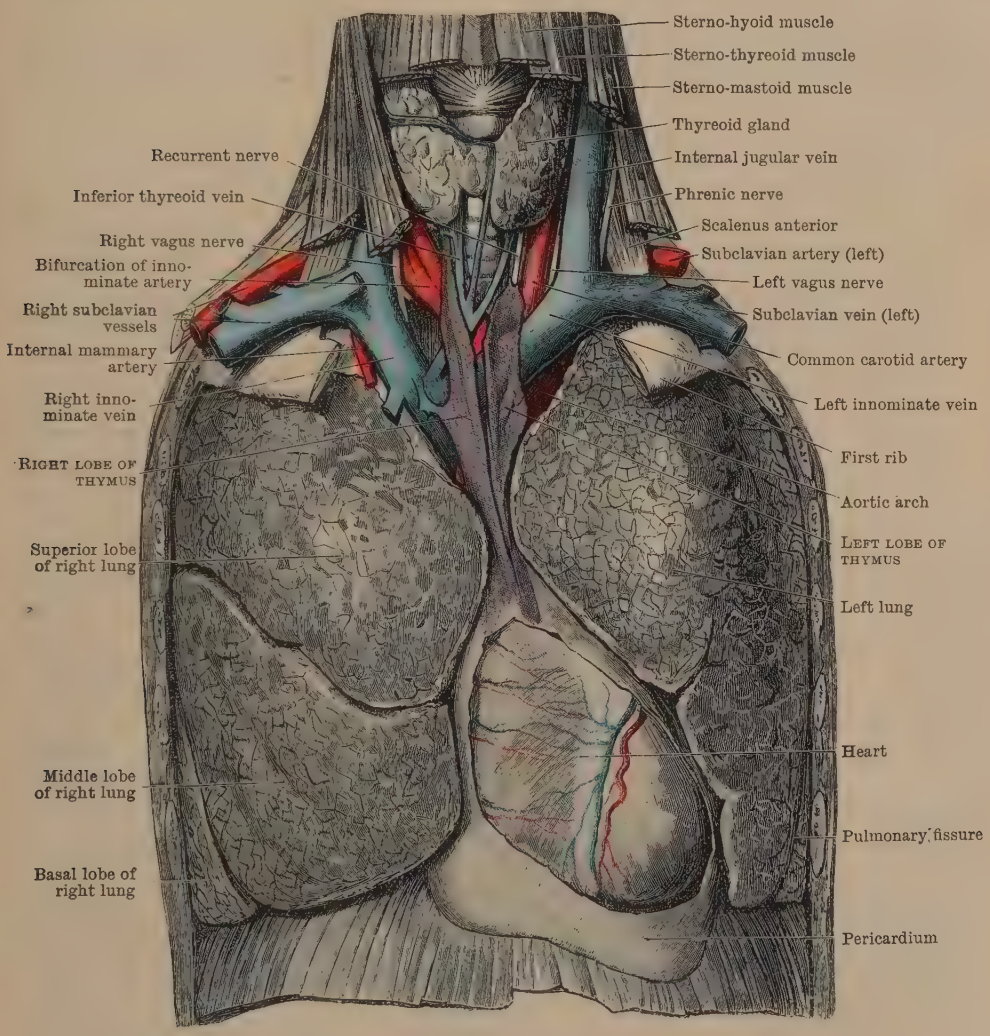

Fig. 1037.—Dissection to show the Thymus Gland in an Adult Female.

The organ, when large, fills all the space available between the pleural sacs laterally, the back of the sternum in front, and the pericardium and great vessels behind; when small it is embedded in fat and fibrous tissue. The shape of the gland varies with its size and the age of the individual. In infants with short thoraces it is broad and squat; in adults with long thoraces it is drawn out into two finger-like strands. It is soft in consistence, and the details of its shape are determined by its size and by the structures upon which it is moulded, viz., the pericardium and the great vessels of the superior mediastinum and the root of the neck. The upper ends of the right and left lobes occasionally extend for some distance into the neck. These "cervical thymus" portions may be elongated and attenuated, and in rare cases may be partially separated from the main mass

of the gland or "thoracic thymus." In other cases the upper parts of the thymus may be connected by a strand of fibrous tissue to the tunica propria of the thyreoid gland, representing an atrophic cervical thymus.

Blood and Lymph Vessels.—The blood supply of the thymus is effected through inconstant branches, chiefly of the internal mammary arteries and their branches. Its veins are irregular and mostly join the internal mammary and left innominate veins. Its lymph vessels are abundant. Although they are not related to the organ in the same manner as in a lymph gland, they have been found filled with lymphoid corpuscles derived from the gland. They enter the mediastinal lymph glands.

Nerves.—Its nerves are minute and are derived from the vagus and sympathetic. The branches of the vagus descend directly to the thymus from about the level of the thyreoid cartilage; the sympathetic fibres run with the blood-vessels. The fibrous capsule of the thymus receives small irregular branches from the phrenic nerves, but these do not supply the gland tissue in any way.

Structure.—The thymus is invested by a fibrous capsule which sends septa into its substance to divide it into lobules. The lobules are similarly divided into follicles (secondary lobules) about 1·5 mm. in diameter. Each follicle consists of a medulla not quite completely surrounded by a cortex. In a general way, the structure of the cortex resembles a lymph gland, but the syncytial reticulum is of entodermal epithelial, instead of mesodermal, origin. The spaces of the reticulum are crowded with lymphocytes, but there are no germinal centres nor lymph sinus. The medulla resembles the cortex, but the reticulum is coarser and contains cell nests, the *concentric corpuscles* of Hassall. As age advances the thymus undergoes involution. This process is marked by an increase of fatty and fibrous tissue and a reduction of the lymphoid parenchyma. The number of lymphocytes and of concentric corpuscles varies with nutrition.

FIG. 1038.—ILLUSTRATING THE CONDITION REPORTED BY GROSCHUFF IN WHICH ACCESSORY THYMUS LOBULES WERE PRESENT.

Development.—As has been stated, there are in reality two thymus glands, a right and a left; they arise from the ventral diverticula of the third pharyngeal pouches. (In the pig a component derived from the ectodermal "cervical vesicle" has been described as entering into the constitution of the embryonic thymus, *Badertscher*). The first indications of the developing glands, cylindrical elongations of the diverticula, are present in 5-mm. embryos; the walls of the cylinders, more particularly their dorsal parts, soon thicken. Coincidently the necks of the pharyngeal pouches become constricted to form the pharyngo-branchial ducts III. These soon disappear, when the thymus rudiments lose all connexion with the pharynx. At this time the upper parts of the rudiments still have a lumen; the lower parts are solid. Soon the lumen vanishes; the solid parts thicken and the developing thymus migrates caudalwards to reach the pericardium at the 15-mm. stage. As a result of the migration the upper part gets drawn out and finally disappears. It is in this process that parathyreoid III. is involved. It is attached to the upper part of the migrating thymus, the part which disappears. The relative time of this disappearance determines the permanent level of parathyreoid III., for until it happens that gland is dragged in the wake of the thymus (see Parathyreoids, Development of). Sometimes a small detached mass of thymus formative tissue may persist beside parathyreoid III., and may differentiate to form an Accessory Cervical Thymus III.

During migration and after, the cells continue to proliferate and the thymus rudiment increases in mass. At the 40-mm. stage lymphocytes begin to appear in it. Differentiation of cortex and medulla is visible at the 45-mm. stage. The details of the process of thymic histogenesis are undetermined. It is believed that the syncytial reticulum and concentric corpuscles are of entodermal origin, but whether the lymphocytes arise *in situ* by metamorphosis of entodermal epithelial cells or are mesodermal immigrants has been the subject of much controversy. The immigration theory may, however, be said to hold the field.

(iv.) The Thymus IV. Vestiges (*vide* Fig. 1038).

Small accessory masses of thymus tissue are in very rare instances found in close relation to parathyreoids IV. They are developed from the ventral diverticula of the fourth pharyngeal pouches in a manner generally similar to that in which the main thymus gland develops from the third. Although extremely rare in man, such accessory thymic derivatives from the fourth pharyngeal pouch are commonly enough met with in various other mammals. They must not be confused with the accessory thymic lobules referred to in the preceding paragraph, which are to be regarded as detached portions of the cervical part of the main thymus. The accessory thymus IV. may, as in some animals (*e.g.* Cat), be enclosed, along with an "internal" parathyreoid IV., in the substance of the thyreoid gland, thus forming a so-called "internal thymus."

(v.) The Ultimo-branchial Bodies (or Post-branchial Bodies).

The fifth pharyngeal pouches give rise to a pair of gland rudiments called ultimo-branchial bodies. Their fate is not known with certainty; it is possible that they may become the strands of parathyreoid-like tissue occasionally present in the lateral lobes of the thyreoid, but it is believed that more frequently they degenerate and leave no vestiges.

Their chief interest is that, for long, they were regarded as the rudiments of the lateral lobes of the thyreoid gland. This belief has since been generally discredited, but *v. supra*, on development of thyreoid, for further discussion of this question.

4. THE CEREBRO-GLANDULAR GROUP.

(i.) The hypophysis (O.T. pituitary body) is a small glandular body of duplex origin and constitution.

It forms a median basal appendage of the pars optica hypothalami, attached a short distance behind the optic chiasma (Figs. 1039, 1040, and 1041). It is lodged in the fossa hypophyseos, occupying the interval between the cavernous sinuses of opposite sides. The cavity in which it lies is lined by the dura mater covering the bone and forming the sinus walls, and it is roofed over by the centrally perforated fold of dura mater known as the diaphragma sellæ (p. 667). Through the small circular aperture in the latter the stalk of the infundibulum connects the hypophysis with the tuber cinereum of the floor of the third ventricle. It is connected with its shell-like capsule of dura mater by areolar connective tissue and blood-vessels.

The hypophysis is flattened oval in form, elongated transversely, and considerably smaller both antero-posteriorly and vertically. Its average dimensions are about 16 × 10 × 6 mm. It weighs about three-fifths of a gramme.

The hypophysis consists of two morphologically different elements, which are also unequal in size. The larger of these originates from the ectoderm of the primitive mouth cavity, and is therefore often distinguished as the "pars buccalis." It forms the lobus anterior, B.N.A., and is also sometimes known as the "glandular lobe" or "pars glandularis." It must be noted that the term "pars anterior" in use by some English writers is not the exact equivalent of "lobus anterior." The latter term should be taken to include the "pars intermedia" as well as the "pars anterior" of these authors.

The *lobus anterior* forms the main bulk of the hypophysis, including as it does the lateral as well as the anterior portions of the organ. It is deeply indented posteriorly forming a notch which accommodates the much smaller posterior lobe. But it also furnishes inconspicuous laminar extensions around the sides and neck of the posterior lobe, the infundibulum, and even on to the tuber cinereum almost as far as the optic chiasma.

As originally developed the lobus anterior or pars buccalis is a hollow sac. The anterior wall of this sac is represented in the mature organ by the solid glandular mass of the "pars anterior" (Figs. 1039, 1041). But the cavity or lumen of the sac does not entirely disappear although it becomes inconspicuous. It continues to be represented by an imperfect cleft-like cavity which seems to separate the

lobus anterior from the lobus posterior but which in reality lies within the lobus anterior, separating its "pars anterior" from its "pars intermedia." The latter forms a cellular lamina of no great thickness clothing the anterior aspect of the lobus posterior and forming the true posterior wall of the cleft-like cavity of the anterior lobe.

This "intra-glandular cleft" is of varying extent in the adult organ and is generally occupied, and more or less interrupted, or even obliterated, by material of colloid character.

The main glandular mass of the anterior lobe is very vascular. In texture it is moderately firm and compact and it is reddish or brownish yellow in tint.

The lobus posterior (Fig. 1039 and Fig. 1041) is much the smaller of the two elements making up the hypophysis. It originates as a diverticulum of the cavity of the forebrain vesicle. The narrow stalk of the diverticulum is preserved as the infundibulum by which the hypophysis is attached to the brain. In accordance with its derivation from the central nervous system the posterior lobe is also known as the "pars nervosa," "pars neuralis," or "cerebral lobe"; the term "pars posterior" has been employed to bring it in line with a "pars anterior" and a "pars intermedia." The term "processus infundibuli cerebri," originally applied to the posterior lobe of the hypophysis by W. Müller, has been adopted by some recent writers but with no very obvious advantage.

"Pars anterior" of anterior lobe

FIG. 1039.—MEDIAN SAGITTAL SECTION OF ADULT HUMAN HYPOPHYSIS.

The lobus posterior is flask-shaped, the body of the flask fitting into the posterior concavity of the anterior lobe, whilst the tapering neck of the flask is continued as the infundibulum to the tuber cinereum of the brain.

In some mammals the posterior lobe is almost completely enveloped by the laminar expansions of the anterior lobe. In man and various other mammals the posterior aspect of the lobus posterior is largely free from such a covering.

The tissue of the posterior lobe is less dense, more friable, more greyish white, and much less vascular than that of the anterior lobe.

In the human fully-developed hypophysis the lobe is solid, but in various other mammals and in the earlier human fœtal period it contains a prolongation of the tubular cavity of the infundibulum which opens above into the third ventricle. In man even the infundibular canal is obliterated except for a short funnel-shaped recess of the ventricle extending into its base and named the recessus infundibuli (Fig. 1040).

Blood-vessels.—The very vascular glandular part of the anterior lobe is supplied by a circlet of small arteries which converge upon it from the neighbouring anterior part of the arterial circle of Willis. These supply blood to the rich net-work of sinusoidal channels which everywhere permeate the lobe and constitute its sole intrinsic vessels. The veins of the anterior lobe more or less correspond with the arteries in their arrangement, entering a venous circle which is drained by the basilar venous system.

The posterior lobe has a much poorer blood-supply. It is derived from an arterial branch formed by the junction of twigs from each internal carotid artery. The veins enter the circular sinus.

The pars intermedia of the lobus anterior is supplied from both of the above sources and also in part from the contiguous part of the brain.

Lymphatics.—The only lymphatic channels within the organ appear to be minute cleft-like spaces between the walls of the sinusoidal channels and the glandular cell masses. Their strictly lymphatic character is at least doubtful.

Nerves.—The anterior lobe has a rich supply from the carotid plexus by way of the arteries. Their terminals have been described as ending in contact with the gland cells.

The posterior lobe is scantily supplied by fibres which reach it along the stalk of the infundibulum.

Structure.—The glandular anterior lobe is composed of anastomosing columns and quasi-follicular groups of cells. The interstices of this cellular sponge-work are occupied by large thin-walled vascular sinusoidal channels with a small amount of connective tissue.

The glandular cells vary in appearance. Some are clear and chromaphobic, others are granular and chromaphilic, but the difference between them may be physiological rather than morphological. Both basiphilic and oxyphilic forms of the granular cell occur.

Globules and small collections of colloid material may be seen, but mainly in the near neighbourhood of the specialised "pars intermedia."

The "pars intermedia" of the lobus anterior consists of a cellular stratum clothing the anterior and lateral surfaces of the proper lobus posterior. It bounds the intra-glandular cleft posteriorly and represents the persistent posterior wall of the embryonic pars buccalis of the hypophysis (Fig. 1041). The cells of this stratum are smaller than those of the main anterior lobe and the structure is less vascular. Globules of colloid material abound and are regarded as the special elaborated product of this region. From it the colloid may be traced into the adjacent posterior lobe.

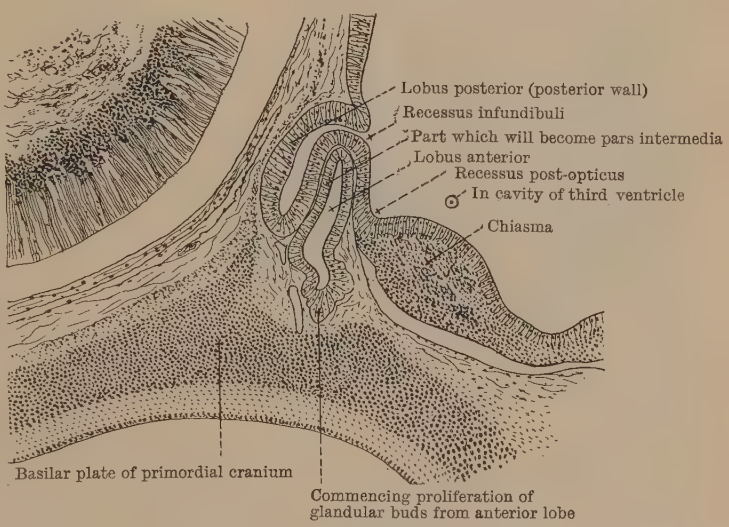

FIG. 1040.—PARAMEDIAN SAGITTAL SECTION OF THE HYPOPHYSEAL REGION OF A HUMAN EMBRYO (20 MM. CR LENGTH).

The posterior lobe consists chiefly of neuroglia tissue, cells, and fibres. There appear to be no nerve cells, and few, if any, nerve fibres. In the vicinity of the pars intermedia the posterior lobe contains groups of immigrant cells derived from the pars intermedia. It also exhibits the colloid masses already referred to. This colloid is believed to reach the cavity of the third ventricle by way of the lobus posterior. It has been shown to be present in the cerebro-spinal fluid.

Development.—As already mentioned, the hypophysis originates from two entirely distinct primordia. Both of these are hollow ectodermal diverticula, one neuro-ectodermal, derived from the floor of the primary forebrain, the other from the surface ectoderm lining the primitive mouth cavity. The latter diverticulum is often known as "Rathke's pouch," and it gives origin to the whole of the lobus anterior or pars buccalis including the pars intermedia. From the former is derived the lobus posterior or pars nervosa (pars neuralis, auct.) together with the infundibulum.

The first trace of the appearance of the hypophysis is met with in embryos of 2-3 mm. in the shape of an angular depression at the bottom of the oral fossa or stomatodaeum immediately in front of the dorsal attachment of the oral (bucco-pharyngeal) membrane. The earliest indication of the infundibular depression from which the neural part of the hypophysis is developed is recognisable in the floor of the primitive forebrain vesicle in embryos of 4-5 mm. In 7-mm. embryos the buccal part of the hypophysis has become a deep diverticulum, but its mouth is still widely open towards the primitive mouth cavity. In the 10-12 mm. stage the deep buccal diverticulum shows some narrowing of its aperture of communication with the exterior. The infundibular recess of the floor of the forebrain vesicle is now more sharply marked, and is somewhat deeper, though still rather insignificant. It is already in contact with the fundus or the posterior wall of the pars buccalis. In 18-20 mm. embryos the diverticulum representing the posterior lobe or pars nervosa has markedly deepened, and is now a rather elongated saccular protrusion of the brain floor, whose anterior wall is in intimate contact with the posterior epithelial wall of the anterior lobe or pars buccalis (Fig. 1040). The previously narrowed duct-like communication of the latter with the buccal cavity has by this time become completely

obliterated and the occluded stalk has become interrupted, so that the hypophysial anterior lobe is separated from the epithelium lining the bucco-pharyngeal cavity. Remnants of the obliterated stalk persist, however, not only at this stage, but up to a much later period of fœtal life, and may sometimes be detected in postnatal life. The obliterated remnant of the stalk is not visible in Fig. 1040, because the sagittal paramedian section illustrated does not pass exactly in its plane. The figure shows very well that between the buccal hypophysial sac and the roof of the bucco-pharynx there is a marked condensation of the mesenchyme, and it is to the establishment in this situation of a basilar plate of condensed mesenchyme that we are to attribute the separation of the buccal hypophysis from the site of its origin in the primitive mouth cavity. Nevertheless, in some few cases this basilar plate of skeletogenous tissue is incomplete immediately around the stalk of the hypophysis, so that a cranio-pharyngeal canal is found later perforating the osseous cranial base and surrounding the remains of the epithelial stalk.

At the stage represented in Fig. 1040 the vesicular lobus anterior of the hypophysis is flattened from front to back. But it is rather widely expanded in the transverse direction, extending considerably beyond the lateral limits of the posterior lobe. Indeed the lateral expansions of the anterior lobe grow backwards around the neck of the infundibular diverticulum so as to embrace it in somewhat the same fashion as the outgrowing atria of the embryonic heart embrace the bulbar cardiac region. Ultimately they meet and fuse around the neck of the infundibular sac. But the vesicular anterior lobe also extends forwards towards the region of the optic chiasma as a lingular prolongation in contact with the post-chiasmatic area of the hypothalamic floor.

Fig. 1041.—Horizontal Section of a Human Fœtus (71 mm. CR Length).

Up to about the 20 mm. stage the wall of the vesicular lobus anterior has preserved its simple epithelial character. Now, however, the anterior wall of it begins to exhibit a process of proliferative budding resulting in the production of a mass of tubular or quasi-tubular cell strands interpenetrated with highly vascular mesenchyme and forming a well-defined and fairly compact structure in place of the former simple epithelial anterior wall of the pars buccalis. The later result of this process as manifested in an embryo of the third month (71 mm. crown-rump length) is illustrated in Fig. 1041. Here the posterior wall of the anterior lobe is seen closely applied to the anterior surface of the posterior lobe, showing very little, if any, proliferative increase in thickness. It is this epithelial lamina which constitutes the pars intermedia, and the 'interglandular cavity" in front of it is simply the flattened lumen of the anterior lobe or buccal portion of the hypophysis. Later still it undergoes further relative reduction and partial obliteration, the cleft or clefts representing it becoming more or less occupied by globules and masses of colloid substance. Compare the sagittal section of the adult organ in Fig. 1039 with the horizontal section of the fœtal structure in Fig. 1041 and note that the plane of the latter section is below the level at which the lateral extensions of the anterior lobe could be seen to encircle the neck of the lobus posterior.

During the course of development from the 20 mm. stage onwards the cavity of the lobus posterior in the human hypophysis tends to become obliterated and finally the lobe becomes solid, as does also the stalk of the infundibulum. The lumen persists in the root of the stalk as the recessus infundibuli of the third ventricle. In the fœtal section through the posterior lobe in Fig. 1041 traces of the occluded lumen are still visible in the central part of the lobe, surrounded by a paler neuroglia zone.

(ii.) Corpus Pineale

(Synonyms: *Pineal gland, Conarium, Epiphysis cerebri.*)

This structure originates as a diverticulum of the roof-plate of the diencephalon. Together with the habenulæ and their commissure and the suprapineal recess, it constitutes the *epithalamus,* B.N.A. (Figs. 512, 1042).

The pineal body is shaped somewhat like a fir-cone (hence the terms pineal and conarium), but is actually a somewhat flattened oval structure, attached in front, but with a free rounded or pointed caudal extremity.

It measures about 10 mm. in length and about 5-7 mm. in thickness. It weighs about one-fifth of a gramme. It is moderately firm in consistence and reddish grey in colour. It is attached by a short, wide, hollow stalk to the extreme caudal portion of the roof of the third ventricle whence it projects caudally, overlapping the tectum mesencephali and occupying the shallow median sulcus between the superior colliculi.

The cavity of the stalk of the pineal body is the recessus pinealis of the third ventricle. It separates the dorsal from the ventral portion of the slightly flattened stalk. The dorsal portion is traversed transversely by a fibre-tract, the commissura habenularum, and is superficially continuous on either side with the tænia thalami. The ventral portion of the pineal stalk forms a reflexed medullary lamina of variable extent, intercalated between the pineal body and the posterior commissure which lies just ventral (morphologically caudal) to it.

Immediately dorsal (morphologically rostral) to the pineal body another recess of the third ventricle, the recessus suprapinealis, extends in a caudal direction in the form of a thin-walled, ependyma-lined, saccular evagination of the tela chorioidea of the third ventricle (Fig. 1042). The inferior (morphologically caudal) wall of this sac is adherent to the upper surface of the corpus pineale which it overlies. Both structures are more or less embedded in the tissue of the surrounding pia-arachnoid, whose relations to the tela chorioidea of the third ventricle are most intimate.

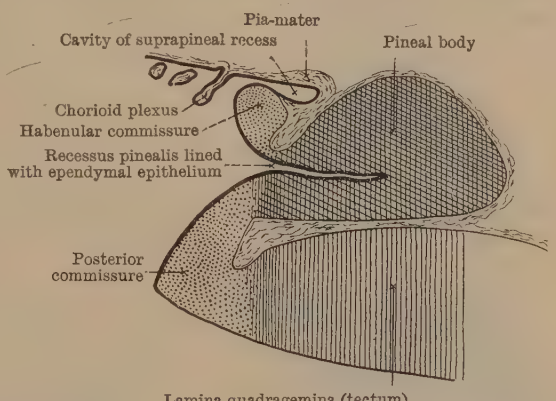

FIG. 1042.—DIAGRAM OF A MEDIAN SAGITTAL SECTION THROUGH THE PINEAL BODY AND ITS IMMEDIATE ATTACHMENTS.

Structure.—From the pial investment of the organ delicate fibrovascular processes and septa extend into its substance. These subdivide it in somewhat irregular fashion into lobular areas (more evident in the newborn than later), and also constitute a fairly dense connective tissue stroma. This supports a parenchyma consisting of more or less regular rounded cell groups or masses. The cellular arrangement to some extent simulates an acinous structure, the subcircular cell formations surrounding clearer areas containing amorphous non-cellular material. The aciniform cell groups are also in part marked out by the meshes of the vascular connective tissue stroma.

Several types of cell are recognisable. The most characteristic of them seems to be that of a large cell with granular cytoplasm and deeply staining nucleus. The granules appear to be of a lipoid nature. Neuroglia cells and fibres of ordinary type are also present in abundance and are readily distinguishable from the large "pineal cells" (the "interneuroglial cells" of Jordan). It is nevertheless possible that these latter are derived from ependyma or neuroglia tissue, or, perhaps more correctly, from the spongioblastic tissue which is the common precursor of both.

Pigment cells and melanin granules, scattered or in groups, are also met with, and the occurrence of plain muscle fibres has been recorded in many animal forms. Calcareous concretions (acervulus, B.N.A., corpora amylacea, "brainsand") are present, often in considerable numbers, throughout the body of the organ as well as in its pial investment and in the neighbouring tela chorioidea. They are more numerous in the adult and are stated to make their appearance first in the septal tissue.

Nerve cells proper appear to be absent from the organ. Some nerve fibres are present. Most of them are non-medullated and they are probably mainly destined for the numerous blood-vessels.

Development and Morphology.—The pineal body originates in the form of a pouch-like evagination of the diencephalic roof immediately in front of the mesencephalon. The epithelial wall of the fundus and greater part of the body of this pouch become much thickened by proliferation of its cells, and thus the lumen comes to be confined to the neck of the organ which becomes the short peduncle. Later, the solid cellular mass of the body of the organ becomes invaded by quasi-diverticular cellular sprouts from the ependymal lining of the recess of the gland. These gradually extend throughout the cellular mass, giving rise to the characteristic

aciniform groups of large pineal cells. At the same time the exterior surface of the body is invaded by the fibrovascular ingrowths from the pia which form the stroma.

A pineal organ is present throughout the entire vertebrate phylum. The "parietal organ" or "parietal eye" met with in some lower vertebrates, particularly in cyclostomes and some reptilia, is frequently referred to as the "pineal eye." It is probable that this is not the exact homologue of the corpus pineale of other vertebrates, which therefore is not to be regarded as a vestigial eye. In some vertebrates, *e.g.* cyclostomes, embryonic rudiments of both organs coexist, though in intimate relationship with one another. The "parapineal" rudiment of the median eye is situated in front of the true "pineal" rudiment. The latter is better regarded as an independently evolved glandular structure, and its persistence throughout the vertebrate series gives some support to the view that it continues to subserve some persistently recurring functional end, probably as an organ of internal secretion.

5. THE LYMPHOID GROUP.

As already stated, *v. supra*, p. 1322, this group should more or less correspond with that of the "glandulæ vasculares" of the B.N.A. But the only member of the group to receive description in this place is the *spleen*.

(i.) Lien.

The **spleen** (B.N.A., **lien**) is a soft, highly elastic, contractile organ of purplish colour, placed in the upper left posterior part of the abdominal cavity, partly in the epigastrium, mainly in the left hypochondrium. It is moulded by the diaphragm, kidney, stomach, and, sometimes, colon. Its dimensions vary widely, but on the average are approximately: length, 12 cm.; breadth, 7 cm.; thickness, 4 cm. The weight is widely variable with the volume. According to a recent investigation (Neugarten), the average weight of the adult healthy spleen is, in the male, 113 gms., and in the female 140 gms. Its shape is modified by the relaxation, distension, and contraction of the neighbouring hollow viscera; its position and the details of its moulding, by the attitude of the individual. It is also subject to substantial physiological variations in volume due to alterations in its blood content associated with variations in alimentary activity.

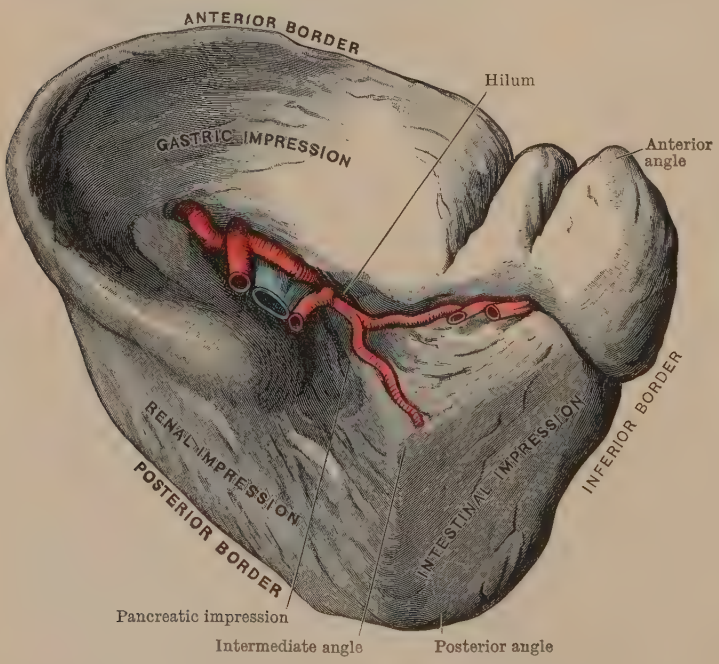

Fig. 1043.—The Spleen—Visceral Aspect.

When the stomach is contracted and the colon distended, the spleen has the form of an irregular tetrahedron; when the conditions of the hollow viscera are reversed, the form of a segment of an orange. These are the extremes of a series of forms which the spleen presents when hardened *in situ*. In the recumbent posture the long axis of the spleen corresponds in direction with the posterior part of the tenth rib; in the erect attitude the long axis is frequently vertical, more especially in adult females.

Surfaces, Borders, and Angles of the Spleen.—The surfaces of the spleen are the facies diaphragmatica, facies renalis, facies gastrica, and, in the tetrahedral form only, facies basalis (colica). Their contour is fairly constant. The **diaphragmatic surface** is convex, moulded to the curve of the diaphragm; the **renal** is slightly concave moulded to the kidney; the **basal** is flat or slightly concave, moulded by the colon; the **gastric**, deeply concave, moulded by the stomach. The gastric surface is interrupted by an irregular, not infrequently divided, slit, the hilum, through which the branches of the splenic artery enter and the tributaries of the splenic vein leave the gland. On the same surface, behind the hilum, there is a depression for the tail of the pancreas.

The borders of the spleen are *margo anterior*, between the gastric and diaphragmatic surfaces; *margo posterior*, between the diaphragmatic and renal surfaces. When present, the basal surface is separated from the diaphragmatic by the *margo inferior*, from the gastric and renal by the *margines intermedii*, *anterior* and *posterior*, whilst another intermediate border also intervenes between the renal and gastric surfaces.

The anterior border of the spleen is almost invariably notched; most frequently there are two notches, but there may be six or seven. Sometimes the posterior border also is notched. Rarely, the notches on the borders are joined by fissures extending across the diaphragmatic surface.

The angles of a tetrahedral spleen are: *superior*, at the junction of the diaphragmatic, gastric, and renal surfaces; *anterior*, at the junction of the diaphragmatic, gastric, and basal surfaces; *posterior*, at the junction of the diaphragmatic, renal, and basal surfaces; *intermediate*, at the junction of the renal, gastric, and basal surfaces. In a spleen of orange-segment form there are but two angles, a superior extremitas superior B.N.A. and an anterior extremitas inferior B.N.A. The superior is bounded in the same way as in the tetrahedral form; the anterior, by the diaphragmatic, gastric, and renal surfaces. In all spleens, but most commonly in those of oblique, irregularly tetrahedral form, the superior angle may curve forward as a blunt hook.

The spleen is entirely covered with peritoneum and is moored by two peritoneal folds, the lieno-renal and gastro-splenic ligaments (pp. 1155 and 1163). Inferiorly it is supported by the peritoneal phrenico-colic ligament (p. 1210).

Small globular accessory spleens are often present. As a rule they are attached to the gastro-splenic ligament near the splenic hilum.

FIG. 1044.—VIEW OF SECTIONAL SURFACE OF ADULT HUMAN SPLEEN, FROM WHICH THE PULP HAD BEEN REMOVED BY WASHING WITH WATER SO AS TO SHOW THE ARRANGEMENT OF THE TRABECULAR AND MAIN VASCULAR STRUCTURES.

Blood and Lymph Vessels.—The spleen receives its blood from the splenic artery, which passes through the lieno-renal ligament. Before reaching the gland it breaks up into six or more branches which enter the hilum independently. Four main branches have been named:—(*a*) art. polaris superior; (*b*) art. gastroepiploica sinistra; (*c*) art. terminalis superior; (*d*) art. terminalis inferior. The vein of the spleen, the splenic vein, is formed in the lieno-renal ligament by the union of several unnamed tributaries which emerge from the hilum. The lymph vessels also leave the spleen at the hilum. They are small and come from the capsule and trabeculæ only, not from the glandular part of the organ. They open into lienal lymph glands placed near the hilum.

Nerves.—The nerves are almost entirely non-medullated and come from the cœliac plexus. They accompany the splenic artery and its branches.

Structure.—The soft and yielding mass of the spleen is encapsuled by peritoneal and fibrous investments and is supported by a fibro-elastic trabecular framework.

The peritoneal covering, tunica serosa, closely invests the organ except where it is reflected on to the lieno-renal and gastro-splenic ligaments and at the hilum. It is very firmly bound to the underlying tunica propria.

The tunica propria (tunica albuginea, B.N.A.) forms a strong fibro-elastic membranous capsule, about 0·1 mm. thick, composed mainly of white fibrous tissue but with a considerable admixture of elastic tissue and also some smooth muscle fibres. From its deep surface rounded or flattened trabeculæ of like constitution pass into the interior of the organ. These are especially strong at the hilum, where they accompany and support the blood-vessels and nerves. The trabecular system appears to be indefinitely and irregularly arranged, but practically its smaller

subdivisions outline small areas of splenic pulp which may be regarded as the anatomical units of the organ. These have been termed by Mall the "lobules" of the spleen. They average about 1 mm. in diameter. They are, however, by no means precisely or completely outlined, and they are irregular in both size and shape.

Each of these rather ill-defined lobular areas is permeated by still finer ramifications of the trabecular system and is traversed centrally by a small artery coming from one of the smaller trabecular arteries. It forms a terminal, or end-artery, not anastomosing with the corresponding vessels in its neighbourhood. Each intralobular artery is surrounded by a periarterial sheath of adenoid reticular tissue whose interstices are packed with lymphocytes. This sheath is prolonged over the vessel as a continuation of the adventitia of the trabecular artery, which it replaces. Here and there, more especially at places of bifurcation of the intralobular artery, the sheath of lymphoid tissue swells out abruptly, and usually eccentrically, to form a small ovoid or spindle-shaped mass of lymphoid tissue, *nodulus lymphaticus lienalis* (O.T. Malpighian corpuscle). On account of the eccentricity of the artery which traverses it, the nodule usually has the appearance of being attached to the side of the arterial wall. Many of the nodules are quite small. Others are easily visible to the naked eye and appear in sections of the organ

FIG. 1045.—REPRESENTATION OF LOW-POWER MAGNIFICATION OF SECTION OF HUMAN SPLEEN.

as whitish specks on the red background of the pulp. They average about one-third of a millimetre in diameter. Several of these lymphatic nodules may occur in the course of the same intralobular artery at successive bifurcations. Ultimately the ten or a dozen arterial twigs resulting from these divisions break up into penicillate groups of very numerous fine arterioles which end by supplying the surrounding pulp tissue. The intralobular artery, together with its lymphatic sheath, may be looked on as furnishing a central branching core for the lobule. The interval between this core and the interlobular trabeculæ is occupied by the splenic pulp in which the terminal arterioles end.

The pulp tissue itself consists of a sponge-like arrangement of splenic cells supported by a fibro-cellular reticulum whose delicate fibres are connected with the ultimate ramifications of the trabecular system.

The cells of the pulp are of various and varying types. These include different varieties of lymphocyte, leucocyte, and erythrocyte. Some are like very large leucocytes and contain the debris of red blood corpuscles. They are to be regarded as splenic phagocytes concerned in the destruction of red blood corpuscles.

Towards their termination the ultimate arterioles of the pulp lose their sheaths entirely and their walls become fenestrated and incomplete. Finally they end in somewhat ampullated channels in the pulp. The veins begin in the same way as the arteries end. The splenic blood therefore flows through a system of "open" intercellular pulp channels which here represent the capillary circulation.

Development.—The spleen is mesodermal in origin. The first indication of its development, in a 9-mm. embryo, is a thickening of the dorsal mesogastrium. In 10-12 mm. embryos the cœlomic epithelium over the splenic rudiment is several layers thick. Soon the deeper layers of the thickening are transformed into mesenchyme and the epithelium is reduced again to a single layer. The first vascularisation of the spleen is effected by a capillary network. Out of this the intra-splenic arteries and veins differentiate. The undifferentiated capillaries between them form capillary tufts or spherules. These become transformed into the pulp. The exact method of this transformation is undetermined, but during its progress great numbers of red blood cells are produced. The lymphatic nodules are developed in the later part of fœtal life, and with their contained lymphocytes differentiate from the tunica adventitia of the arteries.

SURFACE AND SURGICAL ANATOMY.

By Sir Harold J. Stiles, F.R.C.S.

THE HEAD AND NECK.

THE CRANIUM.

Scalp.—The first and third layers of the scalp, namely, the **skin** and the **epicranius muscle**, are firmly united by fibrous processes which pass from the one to the other through the second or subcutaneous **fatty layer**. Intervening between these three layers and the pericranium is a loose **cellular layer** which supports the small vessels passing between the scalp proper and pericranium. The thin **pericranium**, although regarded anatomically as periosteum, possesses limited bone-forming properties; over the vertex it is readily separated from the skull-cap, except along the lines of the sutures, where it gives off intersutural processes to join the external layer of the dura mater.

The free **blood-supply of the scalp** is for the purpose of nourishing its abundant hair follicles and glands. The main vessels lie in the dense subcutaneous tissue, and are superficial, therefore, to the epicranius (Fig. 1046). The arteries supplying the frontal region are derived from the internal carotid, while those for the remainder of the scalp spring from the external carotid. These two sets of vessels anastomose freely with one another, and freely also across the median plane; hence the failure of ligature of the external carotid to cure cirsoid aneurysm of the temporal artery.

Wounds of the scalp bleed freely, and the vessels are difficult to ligature on account of the adhesion of their walls to the dense subcutaneous tissue. In extensive flap wounds and in diffuse suppuration beneath the epicranius there is little danger of sloughing of the scalp. **Abscesses** and **hæmorrhages** superficial to the epicranius are usually limited on account of the density of the subcutaneous tissue. Hæmorrhage beneath the epicranius is seldom extensive on account of the small size of the vessels, but suppuration in that situation may rapidly undermine the whole muscle and its aponeurosis—the galea aponeurotica; incisions to evacuate the pus should be made early, and parallel to the main vessels of the scalp. Extravasation of blood beneath the pericranium leads to a hæmatoma which is limited by the sutures.

The **veins** of the scalp communicate with the intra-cranial venous sinuses—(1) directly through their anastomoses with the large emissary veins, namely, the parietal, which open into the superior sagittal sinus, and the mastoid and condyloid, which open into the transverse sinus; (2) through the anastomoses of the frontal and supra-orbital veins with the ophthalmic vein, which opens into the cavernous sinus; (3) through the veins of the diplöe, which connect the veins of the scalp and the pericranium on the one hand with those of the dura mater and the venous sinuses on the other; (4) through small veins which pass from the pericranium through the bones and the intersutural membranes to the dura mater. It is along these various channels that pyogenic infection may extend, from the scalp and pericranium, through the bone to the dura mater and venous sinuses, and from the latter to the cerebral veins, the pia-arachnoid, and the substance of the brain. More rarely the infection spreads from the cranial cavity along the emissary veins to the scalp.

The **lymph vessels** of the anterior part of the scalp join the external maxillary lymph vessels; those of the temporal and parietal regions open into the pre-auricular and parotid lymph glands, situated in front of and below the ear, and into the post-auricular or mastoid glands, situated upon the insertion of the sterno-mastoid muscle. The lymph vessels of the occipital region open into the occipital glands,

which lie close to the occipital artery and the greater occipital nerve where they become superficial in the scalp. Occipital neuralgia may result from pressure on the nerve by enlargement of one of these glands.

Bony Landmarks of the Cranium.—At the root of the nose is the fronto-nasal suture (**nasion**); a little above it is the **glabella**, a slight prominence which connects the superciliary arches. About 1 in. below the posterior pole of the cranium, and 2 in. above the spine of the epistropheus, is the external occipital protuberance (**inion**). In the child the protuberance is not developed; its position may be defined by taking a point at the junction of the upper and middle thirds of a line extending from the posterior pole of the skull to the spine of the epistropheus. About a third of the distance from the nasion to the inion is the **bregma** or junction of the coronal and sagittal sutures; with the head in the natural erect posture the bregma corresponds to the middle of a line carried across the vertex between the pre-auricular points of the zygomatic arches.

At birth the position of the bregma is occupied by the **fonticulus frontalis**, a rhom-

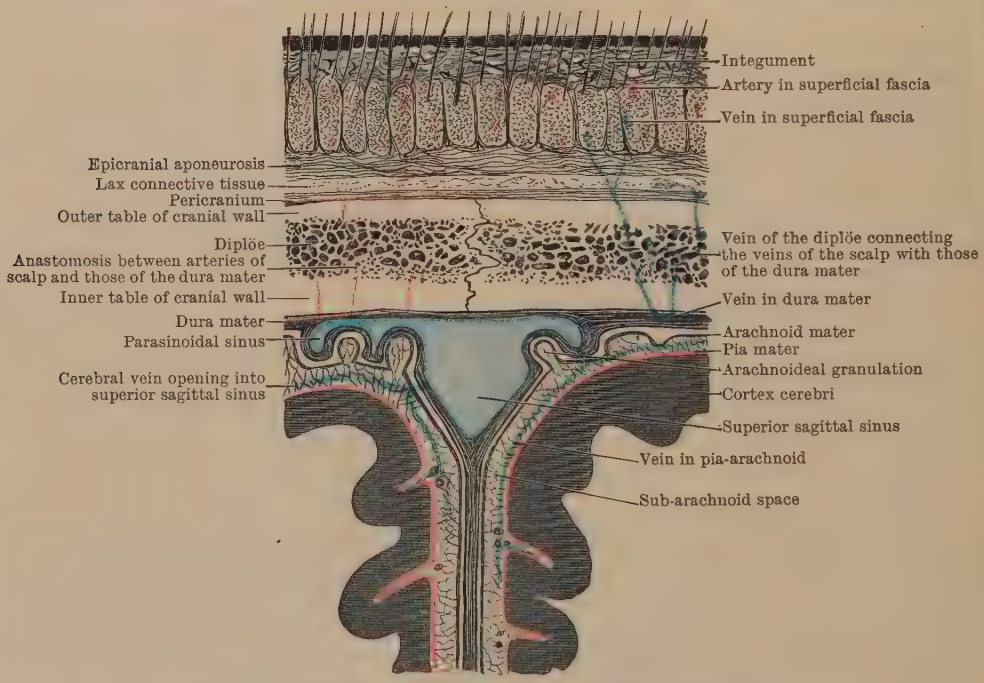

FIG. 1046.—DIAGRAMMATIC REPRESENTATION OF A FRONTAL SECTION THROUGH THE SCALP, CRANIUM, MENINGES, AND CORTEX CEREBRI. (Modified from Cunningham.)

boidal membranous area which generally becomes ossified at about the eighteenth month. The size and date of closure of the fontanelle, as well as its tension and pulsation, are all points to be carefully noted in the clinical examination of children.

The **lambda**, or junction of the sagittal and lambdoidal sutures, situated $2\frac{1}{2}$ in. above the inion, can generally be felt through the scalp; a line drawn from it to the posterior border of the root of the mastoid process corresponds to the **lambdoidal suture**. In the adult the *parieto-occipital fissure* of the brain lies opposite, or a few millimetres in front of, the lambda; in the child, however, the fissure may be as much as 1 in. in front of it.

Crossing the supra-orbital margin close to its medial angle, a finger's-breadth from the medial line, are the **supra-trochlear nerve** and the **frontal branch of the ophthalmic artery**; the latter nourishes the flap in the operation of rhinoplasty. At the junction of the medial and intermediate thirds of the supra-orbital margin, 1 in. from the medial line, is the **supra-orbital notch** or **foramen**, the guide to the **supra-orbital vessels** and **nerves**. A little above the level of the lateral canthus of the eyelid is the **fronto-zygomatic suture**, immediately above which is the **zygomatic process** of the frontal bone. At the posterior end of the suture the

zygomatico-temporal branch of the **orbital nerve** pierces the temporal fascia to reach the scalp. Half an inch above the suture is the **lower margin** of the **cerebral hemisphere**; while half an inch below the suture is a small *tubercle* on the posterior border of the zygomatic bone; a line drawn from this tubercle to the lambda gives the line of the **superior temporal sulcus** and of the **inferior cornu** of the **lateral ventricle.**

The **zygomatic arch**, an important landmark, is horizontal when the head is in the natural position, and is on the same level as the inferior margin of the orbit and the inion; its superior border is at, or not infrequently a little above, the level of the lower lateral margin of the hemisphere. The superior border of the zygoma may be traced backwards immediately above the tragus and the external acoustic meatus to become continuous with the ridge formed by the **supra-mastoid portion** of the **temporal crest.** The part of the posterior root of the zygoma which lies immediately in front of the superior end of the tragus constitutes a valuable landmark which may with advantage be termed the **pre-auricular point** of the zygoma, while by the term **post-auricular point** is understood that point upon the supra-mastoid crest which lies immediately behind, and a finger's-breadth below, the upper attachment of the auricle. The **temporal vessels** and the **auriculo-temporal nerve** cross the zygoma at the pre-auricular point, and it is there that the pulsations of the temporal artery may be felt during the administration of an anæsthetic, or the vessel compressed for the purpose of checking bleeding from the temporal region of the scalp. The termination of the auriculo-temporal nerve in the neighbourhood of the parietal tuber is often the seat of a neuralgic pain in irritative conditions about the external acoustic meatus, the latter being supplied by this nerve.

Two inches vertically above the pre-auricular point is the **inferior end** of the **central sulcus of Rolando.** Two inches vertically above the middle of the zygomatic arch is the **pterion** (spheno-parietal suture), a point which cannot be felt, but which is nevertheless of topographical importance, as it overlies the **lateral point** (the point where the lateral fissure of the brain breaks up into its three branches) and the **anterior branch** of the **middle meningeal artery.**

The **frontal tuber** (better marked in the child) overlies the **middle frontal convolution.** The **parietal tuber**, which varies considerably in the definiteness with which it can be recognised, overlies the **termination of the posterior horizontal limb** of the **lateral fissure of the brain**, and therefore also the **supra-marginal convolution**, which is named by Turner the *convolution of the parietal tuber.* The part of the **temporal crest** which intervenes between the zygomatic process of the frontal bone and the coronal suture lies a little above the level of the inferior frontal sulcus. The highest part of the temporal crest crosses the anterior central gyrus at the junction of its middle and lower thirds, that is to say, at the **junction of the motor areas for the arm and face.** In the child the temporal muscle, which is relatively much smaller than in the adult, reaches only a short distance above the squamous suture, and, therefore, only as far as the level of the inferior end of the central sulcus of Rolando.

The thickness of the skull-cap varies at different parts and in different individuals. The inner table is only half the thickness of the outer table, but both possess the same degree of elasticity. When the vault is fractured from direct violence, the inner table is more extensively fissured than the outer table, because the elements of the latter are compressed, while those of the former are stretched apart. The weak areas at the base of the skull through which fractures are liable to extend are: in the anterior cranial fossa, the orbital parts of the frontal bone, and the cribriform plate of the ethmoid; in the middle cranial fossa, the region of the glenoid cavity of the temporal bone, and of the foramen ovale of the sphenoid; in the posterior fossa, the fossæ of the occipital bone. The strong petrous part of the temporal is weakened by the tympanic cavity and by the deep jugular fossa.

Cranio-Cerebral Topography. — Of the many methods which have been devised for mapping out the relations of the cranial contents to the scalp, that introduced by Professor Chiene is, probably, the most useful from a clinical point of view; no figures or angles have to be remembered, and the primary surface lines are drawn from bony points which are not variable, whilst the secondary lines are drawn, for the most part, between mid-points of the primary lines. The method is as follows (Figs. 1047 and 1049):—

"The head being shaved, find in the median line of the skull between the glabella (G) and the external occipital protuberance (O) the following points:—

"First, the *mid-point* (M); second, the *three-quarter point* (T); third, the *seven-eighth point* (S).

"Find also the *zygomatic process* (E), and the *root of the zygoma* (preauricular point) (P), immediately above and in front of the external acoustic meatus. Having found these five points, join EP, PS, and ET. Bisect EP and PS at N and R. Join MN and MR. Bisect also AB at C, and draw CD parallel to AM."

The line MA corresponds to the **superior** and **inferior pre-central sulci**, and may therefore be termed the *pre-central line*. The *origins* of the **superior** and **inferior frontal sulci** may be indicated by the points of union of the upper and middle and the middle and lower thirds of the line MA, the lower point being at the level of the temporal crest.

The line ET, termed the *oblique* or *lateral line*, intersects the pre-central line at the point A, which overlies the *pterion*, and corresponds therefore to the **lateral point** of the **lateral cerebral fissure** and to the **anterior division** of the **middle meningeal artery**. AC overlies the **posterior horizontal limb** of the **lateral fissure of the brain**, which terminates at the level of the temporal crest, in the inferior part of the triangle HCB. This triangle contains the parietal tuber, and may, therefore, be termed the *supra-marginal triangle*. The termination of the lateral line, at the three-quarter sagittal point T, overlies the **parieto-occipital fissure**.

By joining TR, RO, a triangle is mapped out which delimits the surface of the **occipital lobe**; the line TR corresponds to the **lambdoidal suture**, while RO corresponds to, or lies a little above, the **tentorium** and the upper border of the **transverse sinus**.

CD, the *post-central line*, corresponds to the **superior post-central sulcus**, and lies a little behind the **inferior post-central sulcus**.

The line MA which corresponds to the superior and inferior pre-central sulci affords a ready guide to the Rolandic motor centres.

The pentagon ABRPN maps out the **temporal lobe**, with the exception of its apex, which is directed downwards, forwards, and inwards, a finger's-breadth in front of the point N.

A finger's-breadth below AB is the **superior temporal sulcus**, the posterior extremity of which turns upwards to terminate at B, the point which indicates, therefore, the position of the **angular gyrus**.

The **central sulcus of Rolando** may be mapped out upon the scalp by drawing a line downwards and forwards for a distance of $3\frac{3}{8}$ in. from a point half an inch behind the mid-sagittal point M at an angle of 67° to the sagittal line (Hare). This angle may readily be found by Chiene's plan of folding a sheet of paper first to half a right angle and again to a quarter of a right angle ($45° + 22·5° = 67·5°$). According to Cunningham, the average angle which the fissure makes with the sagittal line is 70°.

Krönlein's scheme for projecting the more important cerebral areas on the surface of the cranium is as follows:—A base line, the same as that advocated by Reid, is drawn from the infra-orbital margin backwards through the upper border of the external acoustic meatus to the occipital region, which it strikes a little below the inion, Fig. 1048. A second line is drawn backwards parallel to it from the supra-orbital margin. Three vertical lines are now projected between these two parallels: the anterior from the centre of the zygomatic arch (C), the middle from the pre-auricular point (D), the posterior from the posterior border of the base of the mastoid process (E). The latter is prolonged upwards to the sagittal line on the cranial vault, and the direction of the central sulcus of Rolando is obtained by drawing a line from this point obliquely downwards and forwards to the point where the anterior vertical meets the superior horizontal line (Sylvian point). The inferior extremity of the sulcus corresponds to the point where the middle vertical line, prolonged upwards, meets the Rolandic line. The lateral fissure line is obtained by bisecting the angle formed by the Rolandic line and the superior horizontal line.

The topographical distribution of function in the cerebral cortex is shown in Figs. 1047 and 1048, in which the areas worked out by Grünbaum and Sherrington in the anthropoid apes have been transferred to the human brain. The above observers have shown that, while the *motor area* occupies the whole length of the anterior

central convolution and of the central sulcus of Rolando (with the exception of its very extremities), it nowhere extends on to the exposed surface of the posterior central convolution; nor does it extend as far down on the medial surface of the hemisphere as the sulcus cinguli. Extirpation of the hand area, for example, is followed by severe paralysis of the hand, but the use and power of the hand is regained in a few weeks; ablations, on the other hand, of even large portions of the posterior central gyrus do not give rise even to transient paralysis.

In some of the animals experimented on, the motor area was found to extend to the deeper part of the posterior wall of the central sulcus of Rolando. Anteriorly it extended into the pre-central sulci as well as into the occasional sulci which cross the anterior central gyrus; indeed the hidden part of the motor area fully equals in extent that contributing to the free surface of the hemisphere. The motor areas extend a little in front of the superior and inferior pre-central sulci, which cannot therefore be regarded as physiological boundaries.

Reference to Fig. 1047 shows that, of the main areas, that for the lower extremity occupies the upper third of the motor region, that for the upper extremity the

middle third, while the face occupies the inferior third. The relative topography of the chief subdivisions of these main areas is shown in Fig. 1048. It must be remembered, however, that there exists much overlapping of the adjacent areas.

The body of the lateral ventricle, which is equal in length to the posterior horizontal ramus of the lateral cerebral fissure, occupies a level midway between it and the temporal line. The anterior horn of the ventricle is opposite the lower part of the coronal suture while the posterior horn is opposite the posterior part of the temporal line. The inferior horn corresponds to the second temporal gyrus.

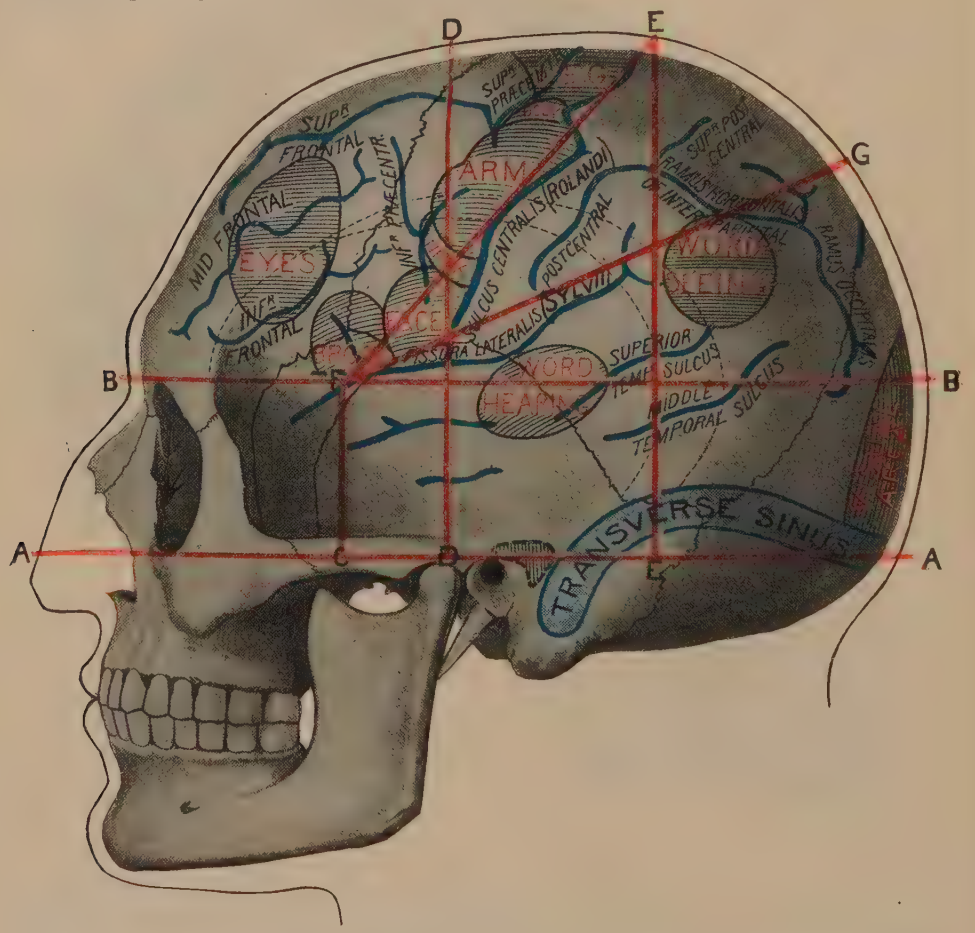

FIG. 1048.—CRANIO-CEREBRAL TOPOGRAPHY ACCORDING TO KRÖNLEIN (motor centres adapted from Grünbaum and Sherrington). Guiding lines, red ; sulci, blue.

The **lateral ventricle** may be tapped or drained from above, by traversing brain tissue for a depth of 4 to 5 cm. through the superior frontal sulcus, $1\frac{1}{4}$ in. (two fingers'-breadth) in front of the point X^2, Fig. 1047, the instrument being directed downwards and backwards (Kocher).

Keen drains the ventricles through an opening $1\frac{1}{4}$ in. behind the external acoustic meatus and the same distance above Reid's base-line (a line drawn backwards from the inferior margin of the orbit through the centre of the external acoustic meatus, X^3, Fig. 1047), the instrument being passed into the brain towards the summit of the opposite auricle. If the ventricle is not distended it will be reached at a depth of two inches from the surface.

To open the **subarachnoid space**, the pin of a small trephine is placed over the mid-point of the line EA, Fig. 1047 ; the dura is incised as it crosses the stem of the lateral fissure of the brain from the frontal lobe to the anterior extremity of the temporal lobe. Care must be taken to keep in front of the middle meningeal artery.

The **cisterna cerebello-medullaris**, situated between the under surface of the cerebellum and the medulla oblongata, may be tapped by turning down a flap of soft parts, and removing a circle of bone immediately above the foramen magnum ; the **fourth ventricle** may be opened up by making a larger opening and separating the posterior extremities of the tonsillar lobes of the cerebellum.

To expose a **hemisphere** of the **cerebellum**, trephine over the centre of a line drawn from the tip of the mastoid process to the external occipital protuberance.

To expose both hemispheres of the cerebellum two flaps are reflected by an anchor-shaped incision. The curved horizontal limb is made a little above and parallel to the superior nuchal line of the occipital bone, and, if possible, the extremities of the incision are kept medial to the mastoid emissary vein, which may give rise to troublesome bleeding. The occipital arteries are divided. The vertical limb of the incision descends medially. As the flap contains the sub-occipital muscles the bone itself may be removed. If more room is required, the opening in the

bone may reach above the level of the transverse sinuses without wounding them, as they can be displaced along with the dura. The occipital sinus is divided between two ligatures. After dividing the dura a hemisphere of the cerebellum may be displaced towards the median plane to enable the finger to be passed between it and the posterior surface of the petrous portion of the temporal bone so as to reach a tumour of the acoustic nerve, which occupies the angle between the cerebellum and the pons.

Meningeal Arteries.—When the calvaria is removed the **meningeal arteries** are found to adhere firmly to the dura mater. Of these vessels the middle meningeal

artery is the only one of surgical importance. It is frequently lacerated in fractures of the skull; the blood is generally extravasated between the dura and the bone, and the bleeding point lies beneath the clot. After entering the cranial cavity through the foramen spinosum, the *main trunk*, which is usually about 1½ in. in length, runs laterally and slightly forwards to bifurcate into anterior and posterior divisions at a point a finger's-breadth above the middle of the zygomatic arch, viz., at or close behind the point N, Fig. 1049. When the main trunk is short the bifurcation takes place opposite the middle of the zygomatic arch.

The *anterior and larger division* passes upwards, with a slight forward convexity, a little behind the spheno-squamosal suture and across the pterion to the sphenoid angle of the parietal bone. From that point the vessel is continued upwards and slightly backwards, behind the coronal suture; it gives off branches which ascend over the motor area. The position and general direction of the anterior branch may be said to correspond to the line MN; it follows, therefore, that the artery will be encountered in trephining over the lower and anterior part of the Rolandic area, especially over the motor centres for the tongue and face.

The *posterior division* passes almost horizontally backwards, towards the mastoid angle of the parietal bone.

To expose the *trunk* of the vessel and its bifurcation, the trephine is applied immediately above the middle of the zygomatic arch. To expose the *anterior division* the pin of the trephine may be applied at the point A, which strikes the artery as it crosses the pterion and grooves the sphenoidal angle of the parietal bone. The inferior segment of the disc of bone removed is much thicker than the superior, as it involves the prominent ridge which passes from the tip of the great wing of the sphenoid on to the sphenoidal angle of the parietal bone. At the sphenoidal angle of the parietal bone, the artery frequently runs in a canal for a distance of half an inch. It follows, therefore, that a considerable thickness of bone has to be sawn through at the inferior segment of the circle before the disc can be removed, and during the removal bleeding may occur from the artery as it lies in the canal.

Vogt localises the *anterior division* at a point a thumb's-breadth behind the tubercle on the posterior border of the zygomatic bone and two fingers'-breadth above the zygoma. Krönlein trephines at a point 1½ in. behind the zygomatic process of the frontal, on a line drawn from the supra-orbital margin backwards parallel to Reid's base-line. If the centre of the trephine be placed at the mid-point of the lower third of the line MA, the anterior division will be reached above the canal and the ridge at the sphenoidal angle of the parietal; if the bleeding-point is lower down, the trephine opening may be enlarged downwards along the line AN.

The course of the *posterior division* may be indicated upon the surface by drawing a line backwards from the point N parallel to PR, that is to say, a finger's-breadth above the zygoma and the supra-mastoid crest.

When the **frontal branch** of the anterior division is injured, the clot is in the fronto-temporal region, and involves more especially the motor area for the face, and, on the left side, Broca's convolution; when the **anterior division** is wounded, the clot, which is larger, involves the parieto-temporal region, and the motor symptoms are due to pressure upon the centres for the arm and face; in injuries to the **posterior division** the clot overlies the parieto-occipital region, and the localising symptoms are sensory (Krönlein). In more extensive meningeal hæmorrhage the clot may cover the greater part of the hemisphere.

The **superior sagittal sinus**, which enlarges as it extends backwards, occupies the median plane of the vertex from the glabella to the internal occipital protuberance, where it opens into the confluens sinuum, and becomes continuous usually with the right transverse sinus. Opening into the sinus, especially in the posterior part of the parietal region, are the **para-sinoidal sinuses**, into which arachnoideal granulations project.

In opening the skull over the posterior part of the vertex, the edge of the trephine should be kept at least three-quarters of an inch from the median plane.

The **transverse sinus** may be mapped out on the surface by drawing a line, slightly convex upwards, through a point a little above the inion to the asterion (1½ in. behind and 1 in. above the centre of the external acoustic meatus) at, or a little in front of, the point R, Fig. 1049, and thence in a downward and forward direction to a point ¾ in. inferior and posterior to the centre of the external acoustic meatus, where it finally curves medially and forwards to open into the jugular bulb, which occupies the jugular foramen. According to Moorhead the highest part of the sinus lies a finger's-breadth above the middle of a line extending from the inion to the middle of the external acoustic meatus. The *anterior border* of

the *descending* or *mastoid portion* of the sinus may be mapped out by drawing a line VW from a point a finger's-breadth behind the post-auricular point of the temporal crest to the anterior border of the tip of the mastoid process. In wounds of the sinus the hæmorrhage is very free, owing to the inability of its walls to collapse, but the bleeding is easily controlled by plugging.

Of the **cerebral arteries**, the *middle* supplies almost the whole of the motor area, and one of its lenticulo-striate branches, which enters the brain at the anterior perforated substance, is called "*the artery of cerebral hæmorrhage*" from the frequency of its rupture in apoplexy. The extravasated blood involves the motor part of the internal capsule. The postero-medial central branches of the *posterior cerebral* artery, which enter the brain at the posterior perforated substance, supply the thalamus and walls of the third ventricle; hæmorrhage from one of these branches is apt to rupture into the ventricle. The postero-lateral central branches of the posterior cerebral artery supply the thalamus, and when one of these vessels ruptures the hæmorrhage is apt to invade the posterior or sensory part of the internal capsule.

Semilunar Ganglion.—The topography of the semilunar ganglion is important in relation to the operation of division of its sensory root for the cure of trigeminal neuralgia. The ganglion is situated between two layers of the dura at the apex of the petrous portion of the temporal bone, at the medial part of the middle fossa of the base of the skull.

The surgeon reaches it by an extra-dural route through an opening immediately above the zygomatic arch. The bone is removed down to the level of the infra-temporal crest, which forms the boundary line between the lateral and basal portions of the middle cranial fossa. The dura mater is separated from the fossa so as to admit of the ligature of the middle meningeal artery immediately after its entrance into the cranium through the foramen spinosum. By separating the dura mater still further in a medial direction the posterior-lateral border of the ganglion is exposed. The raising of the dura is now continued more deeply and at the same time in a slightly backward direction until the dura propria (arachnoid) which covers the sensory trunk of the trigeminal nerve is exposed. By incising this membrane horizontally the cavum Meckelii will be opened into and the nerve will be seen after the cerebro-spinal fluid has escaped; it may then be followed back to its exit from the aperture in the dura mater, which is situated immediately below the attachment of the tentorium cerebelli, between it and the superior margin of the petrous temporal bone. The sensory trunk is now gently raised on a hook and all its bundles must be carefully divided without injury to the small motor root; the latter lies beneath the sensory root. The ganglion has a grayish-red colour and a felted surface, while the portio major or trunk of the trigeminal nerve is almost white, and striated longitudinally.

Ear.—The skin covering the lateral surface of the **auricle** is tightly bound down to the perichondrium, hence inflammations of it are attended with little swelling but much pain. The **posterior auricular artery**, which ascends along the groove at the posterior attachment of the auricle, is immediately anterior to the incision for opening the tympanic antrum.

The cartilaginous portion of the **external acoustic canal**, the general direction of which is medially, forwards, and downwards, possesses various curves of practical importance. The highest part of the upward convexity, which is also the narrowest part of the canal, is situated at the centre of its osseous portion; beyond this the floor sinks to form a recess in which foreign bodies are liable to be imprisoned. Of the two horizontal curves the lateral is convex forwards, the medial concave forwards. The skin of the osseous portion of the canal is thin and fused with the periosteum. Boils in the canal are extremely painful; when situated on the posterior wall and associated with cellulitis the condition may be difficult to distinguish from mastoiditis.

The relations of the osseous walls of the canal are of importance to the surgeon. The whole of the upper wall and the upper half of the posterior wall, developed from the squamous portion of the temporal bone, consist of two layers of compact bone, a superior and an inferior, which are continuous, the former with the inner table, the latter with the outer table of the skull. The superior plate passes medially to the petro-squamosal suture, where it becomes continuous with the lateral edge of the tegmen tympani, which roofs over the epitympanic recess and the tympanic antrum; the lower plate bends downwards and medially at its deepest part to form the lower and lateral wall of the recess and the anterior part of the lateral

wall of the antrum (Trautmann). Upon the upper and posterior segment of the external acoustic margin is the **suprameatal spine**; this small but important process, developed from the squamous portion, can usually be distinctly made out in the living subject by pressing upwards and backwards with the forefinger placed in the external acoustic meatus.

The lower half of the posterior wall of the osseous canal (posterior part of the

tympanic plate) is fused with the anterior part of the mastoid process, and closes the lower and anterior set of mastoid cells (border cells).

Anteriorly and inferiorly the osseous canal is related respectively to the **mandibular articulation** and the **parotid gland**; hence it follows that blows upon the chin may fracture the tympanic plate as well as the base of the skull, that pain on mastication is usually complained of in acute inflammatory affections of the meatus and middle ear, and that in young children, in whom the tympanic plate is incompletely ossified, suppurative inflammation is liable to extend from the parotid region into the external acoustic canal.

Clinically, to obtain a view of the **membrana tympani** a speculum and a reflecting mirror are employed; the auricle is pulled upwards, backwards, and laterally in order to straighten the cartilaginous part of the canal. The healthy membrane is pearly gray, semi-opaque, slightly concave, and obliquely placed, the upper and posterior portion being nearer to the observer than the anterior and inferior part.

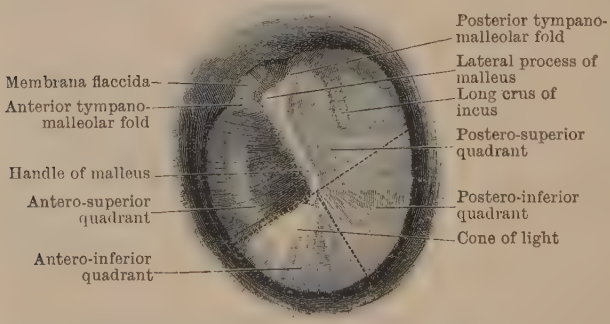

FIG. 1051.—LEFT TYMPANIC MEMBRANE (as viewed from the external acoustic meatus). ×3. (From Howden.)

The handle and lateral process of the malleus, both embedded in the membrana tympani, are the only objects distinctly seen when the healthy ear is examined with the speculum. The lateral process of the malleus projects laterally, and presents itself, therefore, as a distinct knob-like projection at the superior part of the membrane; passing forwards and backwards from this process are the **anterior** and **posterior malleolar folds** of the membrana; they form the lower limit of the pars flaccida of the membrane, and correspond to the line of the chorda tympani nerve. The handle of the malleus, situated at the junction of the two upper quadrants, is seen passing downwards and backwards to the point of maximum concavity of the

membrane (umbo), situated a little below its centre (Fig. 1051); passing downwards and forwards from the umbo is the *triangular cone of reflected light*, to which too much importance must not be attached, since its appearances vary considerably in

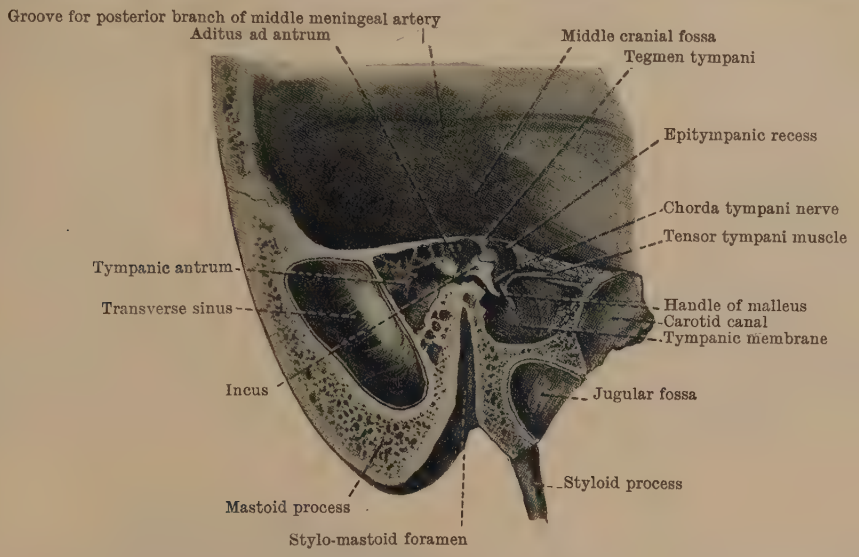

FIG. 1052.—SECTION THROUGH LEFT TEMPORAL BONE, SHOWING TYMPANIC WALL OF TYMPANIC CAVITY, ETC.

healthy ears. Normally, the long crus of the incus is but faintly visible, and still less so are the promontory and fenestra cochleæ; in the condition of obstruction of the auditory tube (Eustachian), however, in which the membrane is indrawn, these structures, along with the folds of the drum-head, become more distinct.

In performing the operation of *paracentesis of the tympanic membrane* the incision is

Showing the relation of the tympanum to the middle and posterior fossæ of the skull.

made through the two posterior quadrants, as, in addition to providing good drainage, it is farthest removed from important structures, especially the chorda tympani nerve.

In order to understand the clinical importance of the parts seen through the translucent membrane, it is necessary to study the relative position of the structure of the

"*mesotympanum*," that is to say, that part of the tympanum which lies opposite the tympanic membrane. If the tympanic plate and the tympanic membrane be carefully removed so as to leave the ossicles and chorda tympani nerve in position, it will be seen that the head of the malleus and the body and short crus of the incus are altogether above the tympanic membrane, and that they occupy the **tympanic attic** or **epitympanic recess** (Fig. 1054). At the junction of the two upper quadrants of the membrane is the **handle** of the **malleus**, which is directed downwards, forwards, and medially; the tendon of the tensor tympani muscle crosses the tympanic cavity from its inner wall to be attached to the upper part of the handle. The **lateral process** of the **malleus** is directed laterally a little below the deepest part of the roof of the osseous external acoustic canal. Opposite the postero-superior quadrant are the **long crus** of the **incus**, which descends behind and almost parallel to the handle of the malleus, and the **stapes**, which is directed medially as well as slightly upwards and backwards to the fenestra vestibuli. The **chorda tympani nerve** runs from behind forwards between the lateral surface of the superior part of the long crus of the incus and the medial surface of the neck of the malleus. At the deepest part of the roof of the osseous canal, above the chorda tympani nerve and the lateral process of the malleus, is a notch (*notch of Rivinus*), which is occupied by the flaccid and highest portion of the membrana tympani (*Shrapnell's membrane*); the notch is due to a deficiency in the tympanic ring which only forms about five-sixths of a circle. Opposite the postero-inferior quadrant of the drum-head is the **promontory** caused by the first part

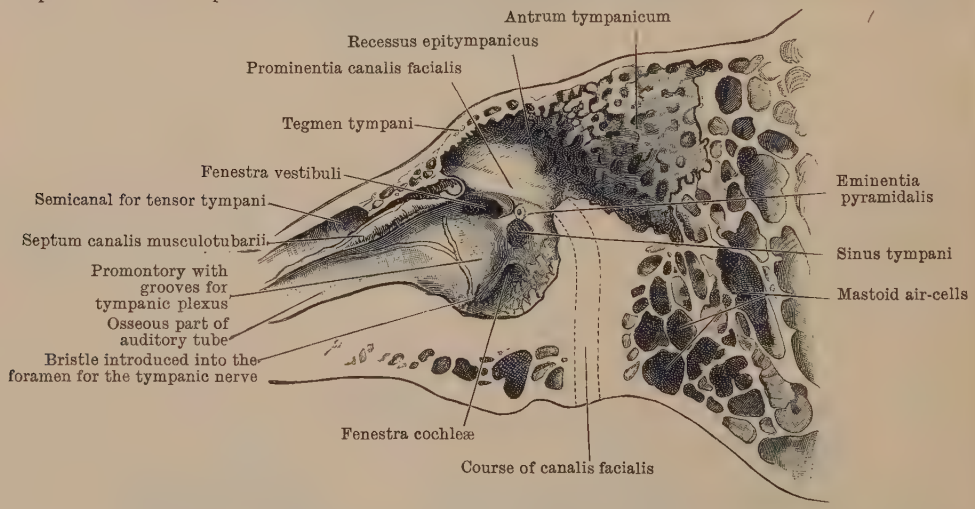

FIG. 1054.—SECTION THROUGH LEFT TEMPORAL BONE, showing labyrinthic wall of tympanic cavity, etc.

of the **cochlea**, below and behind which is the **fenestra cochleæ**. Opposite the antero-superior quadrant are the **processus cochleariformis**, the **tendon** of the **tensor tympani**, and the passage leading towards the **auditory tube**.

The *labyrinthine wall* of the tympanic cavity is related to the internal ear. The *tegmental wall* separated the tympanic cavity from the middle fossa of the skull and the under surface of the temporal lobe of the brain. It is formed by the **tegmen tympani**—a thin plate of bone, which is continued anteriorly to form the roof of the osseous portion of the auditory tube, while posteriorly it roofs over the tympanic antrum. Laterally the tegmen is limited by the **petro-squamous suture**, which may remain unossified for some years after birth, thus affording a channel along which pyogenic infection may spread from the middle ear to the meninges and brain. Infection may also spread along the small veins which convey blood from the tympanum to the superior petrosal and transverse sinuses, and to the posterior fossa of the skull along the vessels which pass from the inner wall of the mastoid antrum through the fossa subarcuata, beneath the dome of the superior semicircular canal.

The *jugular wall* of the tympanum is formed mainly by the bone forming the **jugular fossa**, which is occupied by the bulb of the internal jugular vein. When the transverse sinus is large and unusually far forward the bulb is likewise large, and the fossa, which is consequently deeper, may arch up into the jugular wall of the tympanic cavity, from which it may be separated merely by a thin and translucent plate of bone which occasionally shows an osseous deficiency. In cases where this condition existed the jugular bulb has been wounded in the operation of paracentesis of the tympanic membrane.

Anteriorly the tympanic cavity leads into the **auditory tube**, which brings it into communication with the nasal part of the pharynx. In the child the auditory tube is shorter, wider, and more horizontal than in the adult, hence inflammations are more liable to spread along it to the tympanum.

Above the level of the membrana tympani is the **epitympanic recess**, which communicates posteriorly by means of a triangular opening (*aditus ad antrum*) with the tympanic antrum; the base of the triangle, directed upwards, is formed by the tegmen tympani; its apex, directed downwards, is formed by the meeting of the medial and lateral walls. The opening will admit an instrument half a cm. in diameter. The epitympanic recess contains from before backwards the head of the malleus, the body and short crus of the incus, the latter being attached by a ligament to the floor of the aditus. When these structures are covered with inflamed mucous membrane or granulations, drainage from the tympanic antrum into the tympanum proper is interfered with. The *boundaries of the aditus*, important surgically, are as follows: superiorly, the tegmen tympani; medially, an eminence of compact bone, containing the lateral semicircular canal, inferior and anterior to which is a second smaller prominence, corresponding to that portion of the facial canal which curves immediately above and behind the fenestra vestibuli. The wall of the facial canal is here thin and not infrequently deficient, in which case inflammation may readily spread from the tympanum to the facial nerve. The lateral wall of the aditus is formed by the deepest part of the upper and lateral wall of the osseous external acoustic meatus.

The *posterior wall* of the tympanum, below the aditus ad antrum, is formed by diplöic bone which contains the descending portion of the facial canal. Just below the floor of the aditus, on the posterior wall of the tympanum, is the pyramid, through which the tendon of the stapedius muscle emerges to be attached to the head of the stapes.

The **tympanic antrum** is to be considered, developmentally as well as anatomically, as a backwards and upwards extension of the tympanum (Fig. 1052). Its anatomy and relations will be best understood by studying it in the child, in whom it is relatively larger than in the adult. Situated above and posterior to the tympanic cavity proper, its *lateral wall* is formed by a triangular plate of bone which descends, behind the external acoustic process, from the squamous portion. Posteriorly, this triangular plate is separated from the petro-mastoid element by the **squamo-mastoid suture**, which overlies the posterior part of the antrum and transmits small veins to the surface. The suture does not become completely ossified until a year or two after birth, and remains of it may frequently be detected in the adult bone. The anterior and superior portion of the triangular plate turns medially at an angle to form the upper and posterior wall of the rudimentary osseous canal, as well as the floor of the epitympanic recess.

In the adult the lateral wall of the tympanic antrum is formed by a plate of bone from $\frac{1}{2}$ to $\frac{3}{4}$ in. in thickness, which occupies the triangular and somewhat depressed area between the ridge extending, posteriorly and slightly upwards, from the posterior root of the zygoma (supra-mastoid portion of temporal crest), and the superior and posterior quadrant of the osseous external acoustic meatus; upon the latter is the **supra-meatal spine**, immediately posterior to which, upon the floor of the above triangle, is a crescentic depression, the **fossa mastoidea**. The lateral wall of the antrum is felt through the skin as a slight depression immediately behind the auricle, and immediately inferior to the ridge formed by the supra-mastoid crest; below the depression is the prominence corresponding to the insertion of the sterno-mastoid muscle. Trautmann has pointed out, however, that the supra-mastoid crest, which varies considerably in its obliquity, is sometimes situated a little above the level of the roof of the antrum, and that it is safer, therefore, to take the level of the superior border of the osseous meatus as the guide in order to avoid opening the middle fossa of the skull. In children the supra-mastoid crest is not developed, so that if the operator mistake the posterior root of the zygoma for the crest, he will open into the middle fossa of the skull immediately in front of the epitympanic recess. The upper and posterior quadrant of the osseous meatus is therefore the only reliable guide to the antrum in the child.

The *medial wall* is formed by a thick plate of spongy bone which separates the antrum from that portion of the posterior fossa lying between the aqueduct of the vestibule and the groove for the sigmoid portion of the transverse sinus, and which contains the posterior semicircular canal.

The *roof*, which slopes downwards and forwards, is formed by the posterior and thinnest part of the tegmen tympani.

The *floor* is on a lower level than the aditus, and is therefore unfavourably placed for natural drainage.

The **mastoid process** begins to develop in the second year. As development advances the diplöe surrounding the antrum in the child becomes excavated to form the **mastoid cells**, which radiate from the antrum, and either directly or indirectly communicate with it by small openings. In the pneumatic type of mastoid the whole of the process is excavated by these cells, which extend upwards into the squamous portion, forwards to the posterior wall of the osseous meatus (border-cells), and backwards into the occipital bone. Pus retained within the "*border-cells*" may bulge into, and rupture through, the posterior wall of the osseous meatus. Less frequently the mastoid cells are absent, the bone consisting either of osseous tissue similar to that of the diplöe, or of dense bone (sclerosed type).

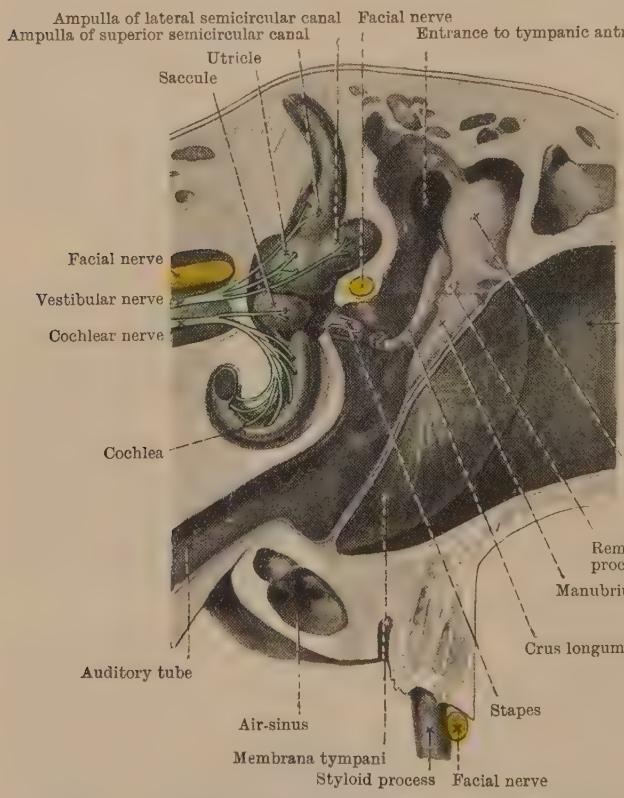

FIG. 1055.—THE TYMPANIC CAVITY AND ADJACENT PARTS (SEMI-DIAGRAMMATIC).

Arthur Cheatle has shown that in the infant the mastoid is composed of sclerotic or sclero-diploëtic bone. The mastoid antrum is always present and there are a few small air cells in its outer wall. In the adult the sclerotic or sclero-diploëtic type of bone persists in about 20 per cent of skulls; that is to say that the outer wall of the antrum is formed of dense bone, or at least dense bone containing marrow spaces. In the remaining 80 per cent the mastoid process is cellular or pneumatic, owing to the extension of the air cells from the antrum into the rest of the mastoid process. This difference in anatomical structure is of great importance in cases of mastoiditis because, if a patient with a pneumatic mastoid suffers from severe otitis media and mastoiditis, the inflammatory process extends to all these air cells and usually comes to the surface on the outer aspect of the mastoid, giving rise to a subperiosteal abscess. On the other hand, if the patient has a sclerotic or sclero-diploëtic mastoid—the so-called "persistent infantile" form of mastoid—the inflammatory process is confined to the mastoid antrum and does not come to the surface and so become manifest. It is in these cases that an attack of acute suppurative otitis media, with infection of the mastoid antrum, is specially liable to become chronic or to result in infection of the labyrinth or an intracranial complication. In operating on cases of chronic middle ear suppuration the surgeon almost invariably meets with the persistent infantile type of mastoid process, for the reason given above. Formerly it was erroneously supposed that

the chronic infection of the mastoid resulted in sclerosis of the bone. We now know, however, that cause and effect have been transposed and that it is the sclerotic type of mastoid which has resulted in the chronic inflammatory condition and not the chronic inflammatory condition which has resulted in sclerosis of the mastoid.

The **labyrinth** may become infected in cases of suppurative otitis media. In acute cases the infective process may pass into the inner ear through the fenestra ovalis or fenestra rotunda. In the former case the annular ligament is infiltrated by pus cells, while in the latter the secondary tympanic membrane is similarly affected. In chronic cases, on the other hand, the route of infection is by way of the prominence of the lateral semicircular canal, which not infrequently becomes eroded in cases of chronic purulent otitis media associated with accumulation of cast off epithelium in the tympanic antrum—a condition known as cholesteatoma. If the labyrinth contains pus it is unsafe to operate on the mastoid unless the inner ear be opened up at the same time. If this is not done the mastoid operation in such cases is likely to be followed by purulent meningitis, owing to the passage of infective material from the labyrinth to the subarachnoid space. The hollow spaces of the labyrinth may be drained by removal of the promontory (see Fig. 1054) by means of a small gouge and two or three blows of the hammer. The gouge is applied just below and in front of the fenestra ovalis, so as to remove the bone between the two windows. In addition, the prominence of the lateral semicircular canal on the

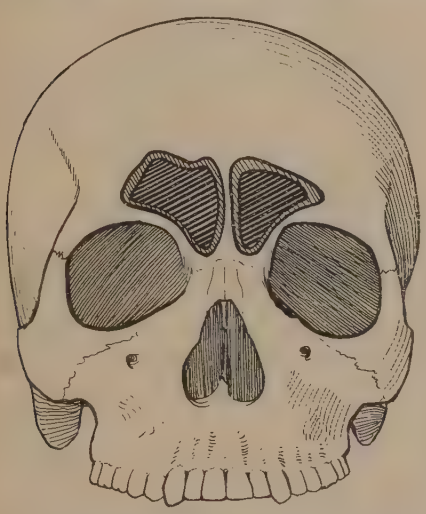

FIG. 1056.—FRONTAL SINUSES OF AVERAGE DIMENSIONS, WITH A MEDIAN SEPTUM. (Logan Turner.)

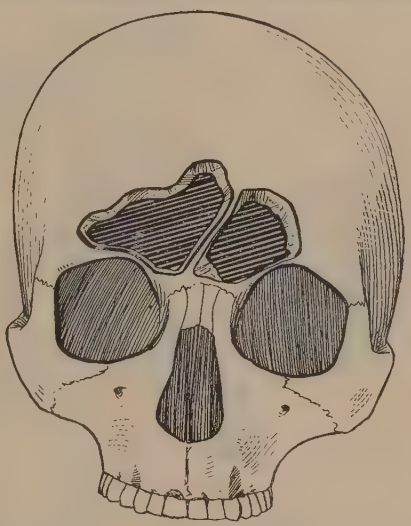

FIG. 1057. — A LARGE RIGHT FRONTAL SINUS WITH SEPTUM OBLIQUE TO THE LEFT. (Logan Turner.)

inner wall and floor of the aditus is usually removed and the canal opened up (Hinsberg's operation). A more radical method is that described by Neumann, in which the sigmoid portion of the lateral sinus is first of all exposed with the large gouge and hammer. A small, blunt periosteum elevator is then passed in between the sigmoid sinus and its bony wall, in an inward and forward direction, so as to separate the dura from the bone in the region of the saccus endolymphaticus. Stacke's protector is then introduced between the dura and the bone and thereafter the bone is removed with the gouge in the direction of the internal auditory meatus. In this way the posterior semicircular canal is first opened up and later the lateral canal is reached. The smooth end of the lateral canal is then followed up to the vestibule, so that the latter cavity is freely drained from behind. In addition, the outer wall of the promontory is chipped off according to the method described above in Hinsberg's operation.

The mastoid portion of the temporal bone is grooved, upon its medial surface, by the sigmoid portion of the **transverse sinus**. The average distance of the foremost part of the sinus from the supra-meatal spine is 1 cm. The right sinus usually receives the superior sagittal sinus, and when this is the case it is larger and farther forward than the left; in extreme cases it may reach to within 2 or 3 mm. of the meatus. The average minimum distance of the transverse sinus from the *outer* surface of the mastoid is about 1 cm., but when the sinus is large and far forward the thickness may be reduced to 1 or 2 mm.

The **facial nerve**, after entering the facial canal at the bottom of the internal acoustic meatus, lies immediately above and behind the fenestra

vestibuli, between it and the prominence of the lateral semicircular canal; thence it descends almost vertically in the mastoid wall of the tympanum $\frac{1}{8}$ in. posterior and medial to the inferior half of the deepest part of the posterior wall of the external osseous canal and emerges through the stylo-mastoid foramen (Fig. 1052).

In the infant, in consequence of the absence of the mastoid process, the exit of the facial nerve from the stylo-mastoid foramen is unprotected and exposed upon the lateral rather than upon the basal surface of the skull, at a point immediately behind the posterior segment of the tympanic horse-shoe. It follows, therefore, that, in infancy, the incision to expose the antrum should not be curved too far downwards and forwards, otherwise the facial nerve may be divided. In the infant the position of the tympanic antrum is relatively higher than in the adult, because in the former the upper wall of the osseous canal inclines towards the vertical plane instead of being horizontal.

The lymph vessels from the auricle and external meatus open into the posterior and anterior auricular lymph glands, the latter receiving also the lymph from the middle ear. The efferent vessels from those glands open into the superior sub-sternomastoid glands; hence it is that those groups of glands are so frequently found to be diseased secondary to tuberculosis of the middle ear; and care must be taken not to mistake an abscess in one of the mastoid glands for sub-periosteal mastoid suppuration associated with middle-ear disease.

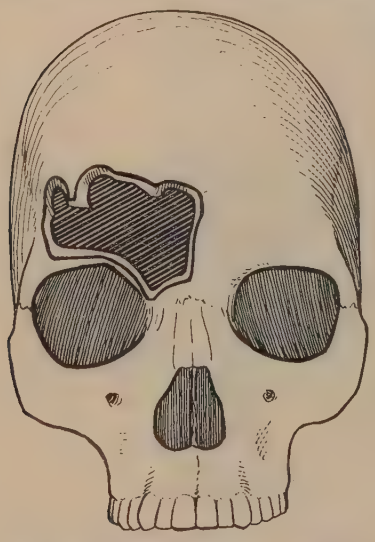

Fig. 1058. — Right Frontal Sinus of very large Dimensions; left Sinus unopened. (Logan Turner.)

To open the **tympanic antrum** the surgeon makes a curved incision a little behind the attachment of the auricle, and removes, with a hammer and gouge, the bone immediately above and behind the postero-superior quadrant of the external osseous meatus. In this operation the *middle fossa* of the *skull* is avoided by keeping below the supra-mastoid crest; the *transverse sinus*, by keeping close to the external acoustic canal and by chiselling obliquely to the surface in opening the mastoid cells; the descending portion of the *facial nerve* is avoided by not encroaching upon the inferior half of the deepest part of the posterior wall of the osseous canal. In extending the operation from the tympanic antrum through the aditus into the epitympanic recess care must be taken not to injure either the *lateral semicircular canal* or the curve of the *facial nerve*, both of which lie in relation to the medial wall of the aditus.

The **frontal air sinuses** are two cavities situated immediately above the root of the nose between the two tables of the frontal bone. Each sinus at its most dependent part communicates, by means of the naso-frontal duct, either directly with the middle meatus of the nose, or indirectly with that channel through its infundibulum. A bony septum, rarely incomplete, separates the two sinuses; it is usually median in position below, but it may deviate to one or other side above (Figs. 1056 and 1057).

The sinuses vary considerably in their size and shape, independently of the degree of development of the glabella and superciliary arches (Fig. 1058). According to Logan Turner, the dimensions of an average-sized sinus are: *height*, $1\frac{1}{4}$ in., from the lower end of the fronto-maxillary suture vertically upwards; *breadth*, 1 in., from the median septum horizontally laterally; *depth*, $\frac{3}{4}$ in., from the anterior wall backwards along the orbital roof. The sinus may exist merely as a recess limited to a small area of bone above the nose, or it may extend upwards on to the forehead for more than two inches; laterally it may be limited by the bony wall of the temporal fossa, while posteriorly it may reach as far back as the optic foramen. The anterior wall is thickest, but the thickness may vary from 1 to 5 mm. The floor is the thinnest wall, hence when pus is retained within the cavity it tends to point at the superior and medial angle of the orbit. Intra-cranial suppuration may arise in connexion with sinus disease by extension through the

cerebral wall. The muco-periosteal lining, which readily strips from the bone, is thin and pale, and provided with mucus-secreting glands.

In many individuals, by the aid of *trans-illumination*, the extent of the sinuses and the position of the intervening septum may be mapped out upon the forehead. For this purpose a small electric lamp is placed against the floor of the sinus, beneath the inner third of the supra-orbital margin.

The skiagraphic appearances of the frontal sinuses are of importance clinically and give more information than trans-illumination. Antero-posterior skiagrams show the vertical extent of the sinus, the degree of asymmetry, and the presence or absence of recesses, with their intervening septum. An orbital expansion is indicated by a well-defined shadow with a sharply-defined upper margin, extending laterally parallel to and immediately above the medial half or more of the supra-orbital margin. A profile skiagram shows not only the height of the sinuses but also their antero-posterior diameter, as well as the degree to which they extend backwards between the roof of the orbit and the

floor of the anterior fossa of the skull, and the relation of the sinus to the underlying ethmoid cells. While it is exceptional to meet with frontal sinuses before the age of five years, they are almost invariably present by the seventh or eighth year.

In exploring the sinus, the opening in the bone should be made close to the median plane, immediately above the root of the nose. In marked cases of deviation of the septum one sinus may extend so far across the median plane of the forehead as to reduce the other to a mere slit; in such cases the surgeon may fail to open the diseased sinus when the operation is performed through the anterior wall. The sinus frequently contains incomplete partitions, which give rise to the formation of pockets and recesses usually found towards the lateral angle of the sinus; when dealing with chronic suppuration of the sinuses, special attention should be paid to these recesses as well as to the backward extension of the cavity along the orbital roof. The **anterior ethmoidal cells** are closely related to the thin medial or nasal portion of the floor of the sinus and its duct of exit; hence suppuration very frequently coexists in both cavities. In some cases pus may flow from the frontal sinus along the infundibulum into the maxillary sinus, which opens at its inferior extremity. Killian's operation for the cure of chronic suppuration in the sinus consists in the removal of its anterior and inferior walls, the supra-orbital margin being left to prevent the falling in of the eyebrow. By removing the frontal process of the maxilla good access may at the same time be obtained to the ethmoidal cells and free drainage established between the frontal sinus and the nasal cavity. (Skiagraphs of Frontal Sinuses, see Plates I. and II.)

In an antero-posterior skiagram of the skull, the light shadows formed by the ethmoidal cells are seen to occupy the well-defined area bounded on either side by the still lighter shadow of the orbital cavities and above by the dense horizontal shadow of the cribriform plate, which occupies the frontier line between these sinuses and the frontal sinuses. Anteriorly the ethmoidal area is overlapped by the vertical shadow caused by the frontal processes of the maxillæ and by the ridges of the lacrimals. Not infrequently the ethmoidal cells will be seen to extend into the roof of the orbit, while inferiorly and laterally they come into close relation to the superior and medial angle of the shadow formed by the maxillary sinus. The comparative transparency of the area of the ethmoidal cells is accounted for by the fact that it is superimposed upon that of the sphenoidal sinuses.

In a profile skiagram the ethmoidal area is seen to extend from the frontal process of the maxilla backwards across the orbits to the sphenoidal sinuses, with which they are contiguous. This area is crossed about its middle by the vertical shadow caused by the lateral margin of the orbit. In front of this, and occupying, therefore, the light area of the orbital cavity, are the anterior ethmoidal cells; while behind it are the posterior ethmoidal cells. In a profile view of the skull, the posterior ethmoidal cells, the sphenoidal sinuses, and the hypophyseal fossa all lie from before backwards in the axis of those rays which pass through the thinnest portion of the cranial box, namely, the anterior part of the temporal fossa; hence the possibility of being able to identify them even in a skiagram taken from a living subject.

The sphenoidal sinuses are so deeply placed behind the upper half of the piriform aperture of the nose that their outlines cannot be identified in an antero-posterior skiagram. If the sinuses be filled with bismuth before the skiagram is taken, it will be seen that they produce a well-defined and slightly oval black shadow, about the size of a shilling, situated opposite the superior half of the piriform aperture, the superior limit of the shadow reaching just up to the transverse curvilinear line already referred to, while laterally the shadow reaches $\frac{1}{2}$ cm. medial to the inferior half of the medial margin of the orbit (Logan Turner).

In a profile skiagram of the skull the light shadow produced by the sphenoidal sinus is seen immediately inferior to and in front of the characteristic well-defined cup-shaped shadow formed by the concave floor of the hypophyseal fossa. Inferiorly the sinus area is bounded and to some extent overlapped and obliterated by the dense shadow which corresponds from latero-medially to the tuberculum articulare and the horizontal portion of the great wing of the sphenoid, that is to say, to the floor of the middle fossa of the base of the skull. This dark shadow is continuous, posteriorly, with that which is caused by the dense petrous portion of the temporal bone. Anteriorly is the shadow of the posterior ethmoidal cells (blurred by that produced by the vertical portion of the great wing of the sphenoid), while posteriorly it is limited by the shadow produced by that portion of the body of the sphenoid which lies inferior to the dorsum sellæ.

Hypophysis Cerebri.

The topography of the sella turcica, which lodges the hypophysis cerebri, is of importance now that surgery has succeeded in dealing with certain tumours and enlargements of this organ. The fossa hypophyseos lies immediately behind the superior part of the sphenoidal sinuses, and, in a median sagittal section of the skull, the anterior half of the fossa is seen to project into what would correspond to the supero-posterior angle of the sinuses (Fig. 146). The more the sphenoidal sinuses project backwards, beneath the sella turcica, the thinner is the plate of bone which separates the sinus from that part of the posterior fossa of the base of the skull which supports the pons. When, on the other hand, the sphenoidal sinuses are small and do not extend backwards below the sella turcica, the latter may be difficult to identify.

The sphenoidal sinuses constitute the surgeon's guide to the hypophysis. To reach them he traverses the upper portions of both nasal cavities, removing,

from before backwards, the upper portion of the septum nasi, the superior and middle conchæ, and, if necessary, the anterior and posterior ethmoidal cells. The rostrum sphenoidale, situated at the superior and most posterior part of the nasal septum, serves as a guide to the anterior wall of the sphenoidal sinuses; after removing it the sinuses are opened up by removing their anterior and inferior walls and the septum. The hypophysis is then exposed by breaking down the anterior portion of the floor of the sella turcica, which forms a bullous-like projection into the superior and posterior part of the sinuses. In making the opening from the sphenoidal sinuses into the hypophyseal fossa, the surgeon must keep strictly to the median plane, so as to avoid opening into the cavernous sinus; if the roof of the sinus be penetrated in front of the fossa the optic chiasma would be injured and the cranial cavity opened, while if the posterior wall of the sinus be penetrated below the level of the fossa hypophyseos the spongy tissue of the body of the sphenoid would be opened into, and if the sinus happened to extend unusually far back, the anterior part of the posterior fossa of the base of the skull would be opened into the basilar artery, adjacent to the ventral surface of the pons, and the cerebral peduncles.

According to Stanley Gibson, the average distance from the nasion to the anterior superior margin of the sphenoidal sinus is $1\frac{3}{4}$ inches, while the distance from the anterior superior boundary of the sinus to the anterior superior margin of the sella turcica is a little more than $\frac{1}{2}$ inch, so that the total distance from the nasion to the hypophysis is from $2\frac{1}{4}$ to $2\frac{1}{2}$ inches. The average distance from the anterior nasal spine to the hypophysis is 7·8 cm. (practically 3 in.), while that from the temporal fossa to the hypophysis is 2 inches. The floor of the hypophyseal fossa occupies a plane $\frac{1}{2}$ inch above the upper border of the zygoma, and is on a level also with a plane projected backwards from the nasion to the inion. The normal fossa varies considerably in size. The antero-posterior and transverse diameters are practically the same, and average 11 mm. (Cope), that is to say, they vary from 1 cm. to $\frac{1}{2}$ inch.

In a profile skiagram of the skull, the outline of the cup-shaped sella turcica is marked out by a crescentic linear shadow, the anterior and posterior horns of the crescent being represented by the shadows of the anterior and posterior clinoid processes. Below and in front of the fossa the outlines of the sphenoidal sinuses may be distinctly traced. In front of the fossa hypophyseos the shadow which outlines the roof of the sphenoidal sinus is formed from before backwards by (1) the tuberculum sellæ, (2) the sulcus chiasmaticus, (3) the plane of the lesser wing of the sphenoid. Above the latter is a second horizontal shadow caused by the roof of the orbit. Below the sphenoidal sinus is a curved shadow produced by the floor of the middle cranial fossa, while behind the dorsum sellæ is the dense triangular shadow corresponding to the petrous portion of the temporal bone. (Plate I.)

Enlargements of the hypophysis cerebri can often be clearly demonstrated by an increase in the depth and antero-posterior diameter of the skiagraphic outline of the sella turcica, by the unusual extent to which the fossa encroaches upon the sphenoidal sinus, by pressure atrophy of the anterior and posterior clinoid processes, and by the thinning and backward inclination of the dorsum sellæ.

Adenomata and cysts of the anterior (glandular) lobe of the hypophysis frequently enlarge upward through the diaphragma sellæ towards the brain. After emerging from the sella the tumour projects through the diamond-shaped space bounded in front by the anterior segment of the arterial circle (Willis), and behind by the optic nerves and the chiasma. The resulting temporal hemianopsia, or complete blindness, is due to the pressure of the growth on the above nerves.

In cases of this kind the tumour must be removed by an intra-cranial operation, which consists in elevating the frontal lobe of the brain after the removal of a portion of the frontal bone. (1) The floor of the anterior cranial fossa, (2) the posterior margin of the lesser wing of the sphenoid, (3) the anterior clinoid process, (4) the optic nerve, (5) the internal carotid artery, (6) the chiasma, and (7) the opposite optic nerve, are, in the order mentioned, the structures encountered successively as the tumour is approached. When, on the other hand, the enlargement of the hypophysis is confined to the hypophyseal fossa, partial removal (decompression) of the growth is carried out by the naso-sphenoidal route.

THE FACE.

The skin of the face is thin, vascular, and rich in sebaceous and sweat glands; it is intimately connected with the subcutaneous tissue, in which are embedded the facial muscles as well as the main blood-vessels. Owing to its elasticity and to the presence of the main blood-vessels in the lax subcutaneous tissue, the face is an admirable site for plastic operations, as the flaps do not necrose in spite of considerable tension. The laxity of the tissues accounts for the marked swelling which attends œdematous and inflammatory conditions about the face. Whenever possible, incisions should be made along the line of the natural furrows and creases of the skin, so as to render the resulting cicatrix less noticeable.

The bony landmarks of the face which may be readily palpated are: the **superciliary ridges** and the **glabella**, the **nasion** (fronto-nasal junction), the **bridge of the nose**, the **osseous piriform opening** and the **anterior nasal spine**, the **supra- and infra-orbital margins**, the **zygomatic process** of the **frontal bone**, the **medial angular process**, the anterior part of the **temporal crest**, the **zygomatic bone**, the **zygomatic arch**, and the region of the **canine fossa** of the maxilla.

Immediately inferior to the root of the zygoma, and in front of the superior part of the tragus, is the **condyle of the mandible**. By pressing with the point of the finger upon the condyle while the mouth is being widely opened, the bone will be felt to glide forwards, while the finger sinks deeply into the hollow corresponding to the **mandibular fossa**. The close relation of the first part of the **internal maxillary artery** to the medial aspect of the neck of the mandible must be kept in mind in operations calling for disarticulation or excision of the condyle. The **ramus of the mandible** is sandwiched between the masseter and the pterygoid muscles, and can be removed without opening into the mouth. Passing downwards from the condyle, one can palpate the anterior and posterior borders of the ramus and the **angle** and **body of the mandible**. The anterior border of the **coronoid process** is felt in front of the upper part of the anterior border of the masseter, immediately below the anterior part of the zygomatic arch.

The pulsation of the **external maxillary artery** may be felt as the vessel crosses the inferior margin of the mandible at the anterior border of the masseter, $1\frac{1}{4}$ in. in front of the angle of the mandible. To map out the course of the artery upon the face, draw a line from this point to a point $\frac{1}{2}$ in. lateral to the angle of the mouth, and thence to a point a little behind the ala nasi and along the side of the nose to the medial angle of the orbit. The **anterior facial vein** lies posterior to the external maxillary artery, and takes a straighter course from the medial palpebral commissure to the anterior inferior angle of the masseter. The vessel is devoid of valves, hence infective phlebitis and thrombosis are liable to spread along it to the cavernous sinus by way of the ophthalmic and pterygoid veins.

A line dropped vertically downwards from the supra-orbital notch (junction of medial and intermediate thirds of the supra-orbital margin) to the inferior border of the mandible opposite the interval between the two lower premolar teeth, will cross the **infra-orbital** and **mental foramina**, the former $\frac{1}{4}$ in. below the infra-orbital margin, the latter midway between the superior and inferior borders of the mandible. In performing the operation of neurectomy for the relief of trigeminal neuralgia, these foramina furnish the guides to the correspondingly-named branches of the fifth nerve. It should be remembered that the nerves in question, after emerging from their respective foramina, lie, in the first instance, beneath the facial muscles. The supra-orbital and infra-orbital nerves are not infrequently represented each by two branches, one of which passes through an accessory foramen situated lateral to the normal opening. Neurectomy of the **inferior alveolar nerve** is performed by trephining the ramus of the mandible midway between its anterior and posterior borders, on a level with the crown of the last molar tooth, the nerve being reached as it enters the inferior alveolar canal: the **lingual nerve**, which lies a little anterior to the inferior alveolar, can be exposed through the same opening.

The relations of the maxillary and mandibular divisions of the trigeminal nerve have become of increased importance to the surgeon since the introduction of the treatment of trifacial

neuralgia by the injection of alcohol into these nerves immediately after their exit from the cranial cavity. According to Symington, in order to reach the maxillary nerve as it lies in the pterygo-palatine fossa, the skin should be punctured immediately below the zygomatic arch, about 4 cm. in front of the anterior wall of the external acoustic meatus. The needle should be directed medially with a slight inclination upwards and backwards. After perforating the masseter and temporal muscles, the instrument enters the fatty tissue of the infra-temporal fossa, embedded in which is the internal maxillary artery and some veins. By passing the needle still more deeply, it is made to penetrate between the two heads of the external pterygoid muscle through the pterygo-maxillary fissure into the pterygo-palatine fossa. If the instrument be passed too far forwards it will strike the maxillary tuberosity; if too far backwards, the lateral pterygoid lamina. The œdema of the eyelids which not infrequently follows the operation is due to some of the fluid passing upwards into the orbit through the inferior orbital fissure. The distance from the skin to the nerve, as it lies in the pterygo-palatine fossa, is practically 2 in. Should the needle, after perforating the masseter, strike the coronoid process of the mandible, the latter may be depressed by opening the mouth.

The mandibular nerve is injected immediately beyond its exit from the foramen ovale, which lies 4 cm. from the skin in the same vertical frontal plane as the tuberculum articulare. When the mouth is opened widely the condyle of the mandible travels forwards and can be distinctly felt immediately below the tubercle. To avoid entering the mandibular joint the needle is introduced through the skin immediately below the zygoma, a little in front of the eminence. It is pushed medially and slightly backwards through the mandibular notch of the mandible, and thence through, or immediately above, the external pterygoid muscle, into the nerve. Symington points out that "the chief dangers connected with this operation are dependent upon the needle being passed in too far. Thus, if it be directed straight inwards beyond the depth of the nerve (4 cm.) it would penetrate the tensor veli palatini and the auditory tube and open on the lateral wall of the naso-pharynx; or, if directed somewhat upwards, it might pass through the foramen ovale, and even reach the cavernous sinus and the internal carotid artery, as the medial boundary of the foramen slopes upwards and inwards."

The **facial nerve**, after emerging from the stylo-mastoid foramen, enters the substance of the parotid gland, nearly an inch deep to the middle of the anterior border of the mastoid process. It is superficial to the external carotid artery. The nerve can be rolled under the finger as it crosses the posterior border of the ramus of the jaw at the level of the lower margin of the tragus; incisions continued along the ramus above this point should be only skin deep if the nerve is to be avoided. To expose the trunk of the nerve an incision is made from the anterior border of the mastoid process to the angle of the mandible. Incisions upon the cheek should, whenever possible, be planned so as to run parallel with the branches of the nerve; these radiate from the inferior end of the tragus. The nerve may be paralysed by wounds of the cheek and by malignant tumours of the parotid, as also by intra-cranial and middle-ear lesions.

The **parotid gland** is surrounded by a fascial envelope, the strongest portion of which is continued from the deep cervical fascia over its superficial aspect to become attached to the zygoma (Fig. 1066); hence abscesses in the parotid tend to burrow deeply towards the pterygo-palatine fossa and the superior part of the pharynx (Fig. 1066); the pus should therefore be evacuated early by Hilton's method, through an oblique incision a little behind and below the angle of the mandible. A study of the relations of the gland explains the surgical difficulties which attend its complete removal.

The **parotid duct** can be rolled beneath the finger as it crosses the masseter, rather less than a finger's-breadth below the zygoma. After winding round the anterior border of the muscle it soon pierces the buccinator, and opens into the mouth opposite to the second molar tooth of the maxilla. The duct corresponds to the intermediate third of a line drawn from the inferior margin of the concha to a point midway between the ala nasi and the margin of the upper lip.

Superficial to the parotid and a little in front of the tragus is the **pre-auricular lymph gland**, which is frequently found to be inflamed in children suffering from eczematous conditions of the eyelids, face, scalp, and external ear. In opening an abscess connected with this gland care must be taken to make the incision as low down as possible, so as to avoid the parotid duct.

The deep parotid lymph glands which lie partly in the substance of, and partly deep to, the inferior part of the parotid, form the highest group of the medial superior deep cervical lymph glands. They are especially liable to become infected secondary to tuberculous disease of the middle ear and to malignant affections about the root

of the tongue, the fauces, and the naso-pharynx. In removing them it is generally impossible to avoid dividing the cervical branch of the facial nerve, which pierces the cervical fascia immediately below and behind the angle of the mandible. This nerve supplies the platysma and the depressor labii inferioris muscles, so that its division gives rise to inability to depress the lower lip on the affected side. At the same operation some trouble may be caused by bleeding from the posterior facial vein and its divisions, which traverse the substance of the gland.

Eyelids.—The skin of the **eyelids**, more especially of the upper, is very thin and connected with the orbicularis oculi muscle by delicate and lax subcutaneous tissue destitute of fat; hence the marked swelling which occurs in a "black eye" and in œdema of the lids. Along the anterior edge of the free margins of the lids are the eyelashes and the orifices of the sebaceous glands, suppurative inflammation of which gives rise to a "*stye*"; along the sharp posterior edge of the free margins are the minute orifices of the **tarsal glands**. These glands, embedded in the deep surface of the tarsi, are seen through the palpebral conjunctiva as a row of parallel, yellowish, granular-looking streaks. From the deep position of the glands it follows that the skin over a Meibomian cyst is freely movable, and that to reach the cyst an incision should be made through the conjunctival surface of the lid.

The **palpebral conjunctiva** is closely adherent to the ocular surface of the tarsi; at the fornix it is loose and contains small lymph follicles, which become hypertrophied in the condition known as granular conjunctivitis. The **ocular conjunctiva** is thin, transparent, and loosely attached to the sclera, so that in operating upon the eye a fold of the membrane can be picked up with forceps to steady the eyeball.

In inflammatory affections of the eye the state of those vessels which are visible gives important information as to the seat of the mischief. For example, in inflammation of the *conjunctiva* the posterior conjunctival vessels (derived from the palpebral arteries), scarcely visible normally, appear as a close network which fades away towards the corneal margin; these vessels move freely with the conjunctiva, and do not disappear under pressure. In superficial inflammations of the *cornea* the anterior conjunctival vessels (the most superficial of the terminal branches of the anterior ciliary arteries) are seen to spread in a freely branching manner into its superficial layers. In *iritis* and deep inflammations of the cornea there is a pink circumcorneal zone of vascular dilatation consisting of delicate straight vessels which disappear under pressure and do not move with the conjunctiva; they are the subconjunctival (episcleral) terminations of the anterior ciliary arteries; in health they are invisible.

Lacrimal Apparatus.—The **lacrimal gland**, situated behind the lateral part of the supra-orbital margin, cannot be felt unless enlarged. By everting and raising the upper eyelid, the accessory (palpebral) portion of the gland is seen to project beneath the lateral third of the fornix, in which situation also the minute orifices of the lacrimal ducts may be detected. By gently drawing downwards the lower lid, the small **punctum lacrimale** is seen situated upon a slight papillary elevation of its margin about 4 mm. from the medial palpebral commissure; the corresponding orifice of the upper lid is placed a little nearer the commissure. Normally the puncta are directed towards, and accurately applied to, the ocular conjunctiva immediately lateral to the lacrimal caruncle. By drawing the lids laterally the **medial palpebral ligament** is put upon the stretch, and can be felt as a narrow tense band passing transversely medially to be attached to the frontal process of the maxilla. The ligament is a guide to the position of the **lacrimal sac**, which it crosses a little above its centre. Continuous with the inferior end of the lacrimal sac is the **naso-lacrimal duct**, which passes downwards and slightly backwards and laterally, to open into the inferior meatus of the nose, under cover of the anterior end of the inferior concha. The lacrimal sac and naso-lacrimal duct each measure about ½ in. in length; the latter is slightly contracted at its commencement and termination, and it is in these situations that pathological strictures of the duct are commonest. Spontaneous rupture of an abscess of the lacrimal sac almost invariably occurs just below the medial palpebral ligament; it is in this situation that the abscess should be opened, the incision being made a little lateral to the angular termination of the external maxillary artery.

The **canaliculi lacrimales**, which convey the tears from the puncta to the lacrimal sac, run for the first 1-2 mm. almost vertically to the free margins of the lids, and thence parallel to them. Between the canaliculi is the **lacrimal caruncle**. In the various morbid conditions which give rise either to misdirection of the puncta or to stricture at any part of the lacrimal drainage apparatus, overflow of the tears (*epiphora*) is the chief symptom. In passing a probe along a canaliculus the instrument, in consequence of the bend upon the duct, is passed at first vertically to the margin of the lid, and afterwards parallel to it, until the point is felt to strike against the medial wall of the lacrimal sac; to pass the instrument onwards along the naso-lacrimal duct the handle is rotated forwards and upwards through a quarter of a circle, and then pushed gently downwards and slightly backwards and laterally into the inferior meatus of the nose.

The **tarsi** are attached to the periosteum of the orbital margins by the **superior** and **inferior palpebral ligaments** which shut off the communication between the subcutaneous tissue of the eyelids and the fatty tissue of the orbital cavity. In fracture of the anterior fossa of the base of the skull involving the orbital part, the blood extends forwards between the periosteum and the musculo-fascial envelope of the orbit and appears under the conjunctiva.

To obtain free access to the cavity of the orbit, the surgeon first enlarges the palpebral fissure by making a horizontal incision from the lateral palpebral commissure to the lateral margin of the orbit, and then, after everting the eyelid, divides the conjunctiva along the fornix of the upper or lower lid, or of both, as may be desired.

Nose.—To examine the anterior nares (*anterior rhinoscopy*) a strong light is reflected into the nostril, which is dilated by means of a nasal speculum. The **anterior extremity of the inferior concha** appears as a rounded body projecting from the lateral wall of the nose; in turgescence of its erectile tissue it is liable to come in contact with the nasal septum and so occlude the nostril. The **inferior meatus**, situated between the inferior concha and the floor of the nasal cavity, is brought into view by tilting forwards the head. The **inferior aperture of the naso-lacrimal duct** is concealed from view by the anterior part of the inferior concha. The **floor** of the nose is horizontal and placed on a slightly lower level than the anterior nares. The **septum**, generally more or less deviated to one or other side, is seen when the head is slightly rotated away from the side to be examined. The **anterior extremity of the middle concha**, which lies a little behind and medial to the lower-medial angle of the orbital margin, is seen when the patient's head is thrown well back; between it and the septum is a slit-like interval (*olfactory cleft*). By rotating the patient's head towards the corresponding shoulder the **anterior part of the middle meatus** is brought into view; pus in that situation may originate from the frontal, the anterior ethmoidal, or the maxillary sinuses, all of which open into the middle meatus.

To make a satisfactory *digital exploration* of the anterior part of the nasal cavities, it is necessary to divide the columella and the cartilaginous septum with a strong pair of scissors, one blade being introduced into each nostril (Kocher); blood spurts from the small arteries of the septum, but the bleeding soon ceases. When these vessels, which are derived from the superior labial arteries, are the source of the hæmorrhage in epistaxis, the bleeding can be arrested either by compressing the superior labial arteries, by plugging the anterior nares, or by grasping the cartilaginous part of the nose firmly between the finger and thumb.

The **maxillary sinus** (O.T. **antrum of Highmore**), situated in the maxilla, is a pyramidal cavity with its base formed by the lateral wall of the nose and its apex directed towards the zygomatic bone. The cavity is lined by a thin muco-periosteal membrane, easily separable from the bone; in the mucous layer are numerous mucous glands from which cysts may develop. The floor of the sinus, which is at or a little below the level of the floor of the nose, is separated from the roots of the premolar and molar teeth by a plate of bone of varying thickness. When this plate is thin and devoid of spongy bone, the floor of the sinus sinks below the level of the floor of the nose, and suppuration at the roots of one of the teeth above mentioned is, in these circumstances, very liable to extend to the sinus. In a sinus of average dimensions the line of union of the nasal and facial walls of the cavity corresponds externally to the lateral edge of the canine ridge (Logan

Turner). The *nasal orifice* is situated at the highest part of the sinus, and is therefore unfavourably placed for natural drainage; it opens into the posterior and lower part of the infundibulum, which in its turn communicates with the middle meatus of the nose through the *hiatus semilunaris*. In a varying percentage of heads a second communication exists between the sinus and middle meatus, the opening being situated posterior to and below the normal orifice; when this accessory aperture exists, pus from the sinus may drain backwards into the nasal part of the pharynx (Logan Turner).

In *empyema of the sinus* the opening to evacuate and drain the cavity may be made—(1) Through the alveolus of the second premolar or of the first or second molar tooth, the first molar being the site of election; this route is now seldom made use of. (2) Through the canine fossa, lateral to the prominence caused by the root of the canine tooth. (3) Through the lateral wall of the inferior meatus of the nose.

In an antero-posterior skiagram of the skull, the shadow of the maxillary sinus presents a pyramidal outline, the base corresponding to the floor of the orbit and the rounded apex to the alveolar recess of the sinus. Sometimes the floor of the sinus extends medially, below the floor of the nose, into the palatine process of the maxilla so as to form a distinct palatine recess. The medial outline of the sinus area is formed by the foreshortened shadow of the nasal wall of the sinus and the lateral pterygoid lamina, while laterally it is outlined by the zygomatic bone. The petrous portion of the temporal bone throws a deep shadow across the superior half of the sinus. In taking the skiagram, therefore, the head should be placed in such a position that this shadow is raised as much as possible into the orbits. In the living subject the inferior and medial portion of the outline of the maxillary sinus is considerably obscured by that caused by the cervical portion of the vertebral column (Killian).

In a profile skiagram of the facial region of the dried skull, the shadow of the outline of the maxillary sinus is well defined. It is represented below by the dense horizontal shadow of the hard palate which crosses the tips of the roots of the molar teeth. Above it is limited anteriorly by the dark curved shadow of the floor of the orbit, while above and posteriorly is the shadow of the posterior ethmoidal-cell area. Behind the maxillary area are the vertical linear shadows of the pterygoid laminæ overlapped by that of the coronoid process of the mandible. The anterior part of the sinus area is overlapped and, to a considerable extent, obscured by the shadow caused by the denser and somewhat triangular shadow of the zygomatic bone.

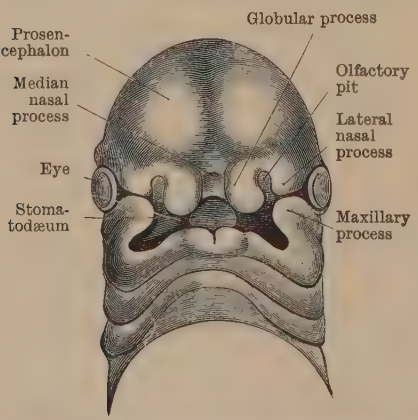

Fig. 1060.—Head of Human Embryo about 29 Days old, showing the division of the lower part of the median nasal process into the two globular processes, the intervention of the olfactory pits between the median and lateral nasal processes, and the approximation of the maxillary and lateral nasal processes, which, however, are separated by the oculo-nasal sulcus. (From His.)

Lips. — In compressing the **labial arteries**, it must be remembered that they run under cover of the mucous surface, a short distance from the free margins of the lips. The lips are abundantly supplied with **mucous glands** which can be felt immediately beneath the mucous membrane nearer their attached than their free borders; the glands are a frequent source of mucous cysts; occasionally they are enlarged congenitally, giving rise to one form of hypertrophy of the lip.

Hare-lip is due to failure of the union of the superficial parts of the median nasal subdivision of the fronto-nasal process with the maxillary process (Fig. 1060). The deformity is spoken of as complete or incomplete according as the cleft extends into the nostril or merely involves a portion of the lip. The fissure may involve the lip only, or it may include the alveolar process of the maxilla; in the latter case the cleft may or may not be associated with a cleft of the palate

Lastly, the hare-lip may be single or double, according as the deficiency has occurred on one (usually the left) or both sides.

Fig. 1061, taken from a coronal section through the head of a human embryo at the seventh week, shows how the mouth is shut off from the nasal cavities by the growth inwards from the deep aspect of the maxillary process of two horizontal plates (palatine processes) which unite in the median line with each other and with the inferior border of the septum of the nose; the latter, which develops as a downgrowth from the primitive basis cranii, is continuous anteriorly with the two medial nasal processes which form the premaxillæ and the median portion of the upper lip. The various degrees of *cleft palate* are due to the more or less complete failure of union of the palatine processes with each other and with the premaxillary part of the median nasal processes. The cleft in the soft palate, which is always median, may be either partial or complete, and may or may not extend forwards into the hard palate. The cleft in the latter is spoken of as single or double according to whether the palatal processes have failed to unite with the lower edge of the nasal septum on one, or on both, sides. When the cleft extends forwards through the alveolar process to become continuous with a cleft of the lip, the medial (premaxillary) edge of the cleft is usually projected forwards in advance of the lateral (maxillary) edge. Before proceeding to repair the cleft in the lip, the projecting premaxillary edge is forced back into line with the maxillary edge.

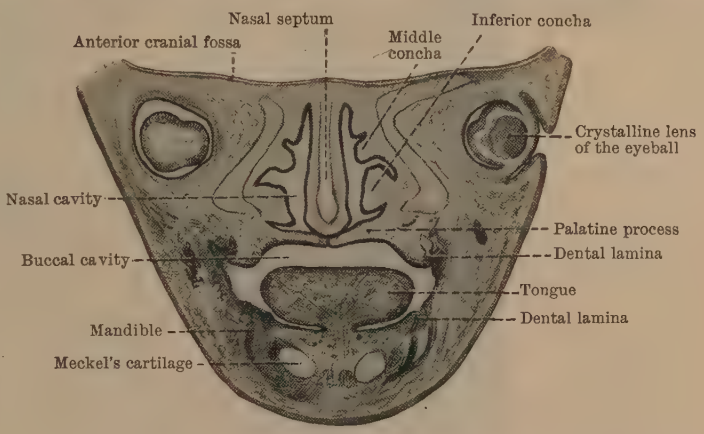

Fig. 1061.—Frontal Section through the Face of a Human Embryo at the Seventh Week.

In what is known as a complete double cleft palate, the palatine processes fail to join the nasal septum and the premaxillæ on both sides; the result is a wide median cleft which communicates with both nasal cavities. The free inferior border of the vomer extends along the middle of the cleft to be continuous anteriorly with the rounded premaxillary mass; the latter, along with the central portion of the upper lip, is projected forwards between the two labial clefts, often to such an extent that it appears to spring from the tip of the nose (Fig. 1062). In operating on such a double hare-lip the first step is to get rid of the premaxillary projection. This is done, not by removing it altogether, but by removing a triangular portion of the septum of the nose behind it, so as to allow of its being bent back into line with the alveolar processes of the maxillæ. The base of the triangular piece of bone should not be taken from the constricted portion of neck of the premaxillary projection, but should consist of the olive-shaped thickening situated immediately behind the neck. This thickening is crossed by the transverse suture uniting the premaxilla with the anterior extremity of the vomer (Fig. 1063). If the premaxillary projection be removed altogether, there is nothing left to support the upper lip, and the result is an ugly deformity, due to the comparative protrusion and redundancy of the lower lip.

Teeth.—The **milk teeth** begin to appear from the sixth to the eighth month, the first to emerge being the lower central incisors. The first dentition is completed about the thirtieth month. Delayed dentition is generally due to rickets. Of the **permanent set** the first to erupt are the first molars, which appear at the end of the sixth or seventh year; the third molars, the last to appear, may erupt any time between the eighteenth and the twenty-fifth year, or even later. As the permanent teeth push their way towards the surface, absorption of the roots of the first set takes place, and the first set either fall out of their own accord or are easily removed. Loss of the permanent teeth is followed by absorption of the alveolar margin of the jaw. The tooth sockets are lined by a thin periosteum, which is anatomically continuous with the pulp tissue of the teeth on the one hand and the dense fibrous tissue of the deep layer of the gum on the other.

The upper incisors and canines and the lower premolars have *cylindrical* roots, hence in extracting those teeth they should be first loosened by a slight rotatory movement; the roots of

the lower incisors and canines and of the upper premolars are *flattened*, so that they must be loosened by a lateral movement. The roots of the third molars are *convergent*, generally welded together and curved backwards, especially in the mandible. The first and second upper molars have three roots which are often *divergent*.

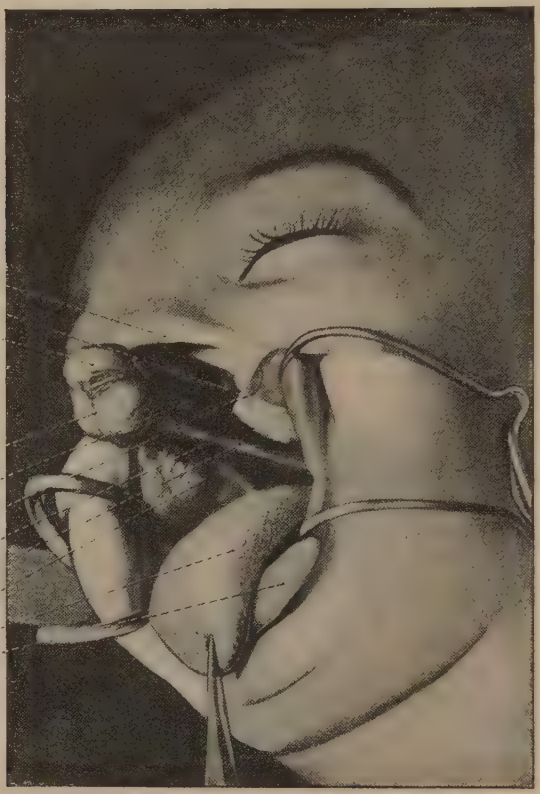

FIG. 1062.—FROM A PHOTOGRAPH SHOWING DOUBLE COMPLETE HARE-LIP AND CLEFT PALATE.

Tongue.—For practical purposes, as well as on developmental and structural grounds, it is convenient to divide the tongue into an anterior two-thirds—the **oral part**, and a posterior third—the **pharyngeal part** (Fig. 1066). At the junction of the two portions, immediately behind the median vallate papilla, is the **foramen cæcum**, which represents the remains of the upper or pharyngeal extremity of the **thyreo-glossal duct**. *Congenital cysts* and *fistulæ* which develop from persistent remains of this tract are always median; those arising from the upper or lingual portion of the tract are situated above the hyoid bone, whereas those developed from the lower or thyreoid portion are situated below the hyoid bone. The liability of these cysts and fistulæ to recur after operation is due to the fact that part of the epithelial tract lies in the substance of the hyoid bone.

The mucous membrane covering the pharyngeal part is much more sensitive than that covering the oral, hence in using a tongue depressor the instrument should, except under special circumstances, rest only upon the latter region, otherwise a reflex arching of the tongue will be set up, which prevents the operator from obtaining a satisfactory view of the throat. Scattered over the pharyngeal part are clusters of **lymph follicles** (lingual tonsils), which appear on the surface as a number of nodular umbilicated elevations provided with little crypts into which mucous glands open (Fig. 1066). The lingual tonsils are liable to chronic inflammation and hypertrophy, conditions which are often accompanied by a varicose condition of the veins which lie immediately beneath the mucous membrane containing the palatoglossus muscle. To obtain a satisfactory view of the lingual tonsils in the living subject the laryngoscopic mirror must be employed.

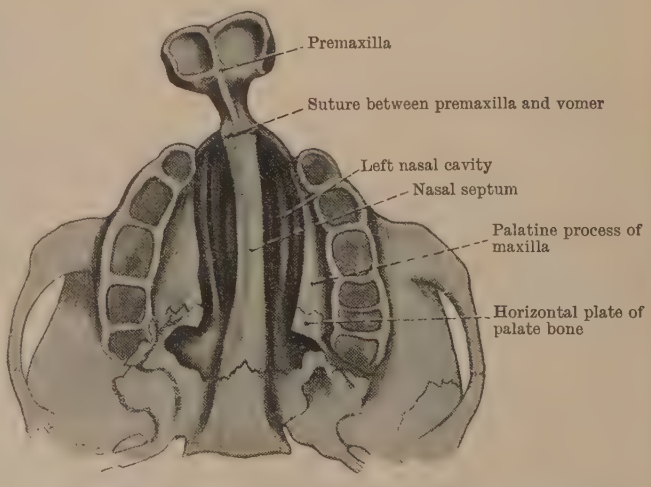

FIG. 1063.—SHOWS ARRANGEMENT OF BONES IN DOUBLE CLEFT PALATE. (*Handbook of Practical Surgery*, Bergmann, Bruns, and Mikulicz.)

The pair of mucous glands situated on the inferior surface of the tongue a little behind its tip, and known as the **anterior lingual glands**, are of interest in that they occasionally give rise to mucous cysts similar to those which develop in connexion with the labial glands (Fig. 1065).

The **muscular bundles** of the tongue are separated by a quantity of loose connective tissue, rich in blood- and lymph-vessels (Fig. 1064); hence acute inflammatory œdema of the substance of the tongue may be attended with a degree of swelling sufficient to obstruct the respiratory passage.

The main **blood-vessels** of the tongue run from behind forwards, nearer its inferior than its superior surface (Fig. 1064); incisions into the substance of the tongue to reduce swelling and tension should therefore be made longitudinally upon the dorsum. Bleeding from the lingual artery, divided in the substance of the tongue, is temporarily arrested by passing the finger behind the base of the tongue and hooking it well forward, so as to compress the vessel against the lingual surface of the mandible. On account of the very slender anastomosis between the vessels of the two halves of the tongue, scarcely any bleeding occurs when the organ is split in the median plane.

According to Poirier, the collecting trunks which arise from the lymph net-

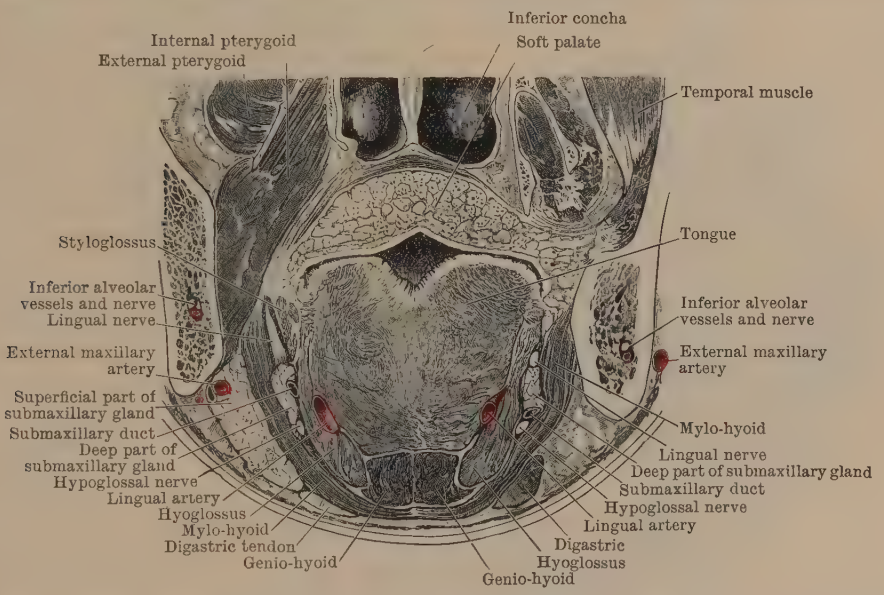

FIG. 1064.—FRONTAL SECTION THROUGH THE TONGUE AND SUBMAXILLARY REGION IN A PLANE BEHIND THE MOLAR TEETH. (From Cunningham.)

works in the mucous membrane and muscular substance of the tongue may be divided into four groups:—(1) **Apical trunks** which open partly into the submental glands and partly into a gland of the medial deep cervical group lying immediately above the anterior belly of the omo-hyoid muscle. (2) **Marginal trunks** which pass, some lateral to the sublingual gland and through the mylo-hyoid muscle, to join the most anterior of the submaxillary lymph glands; others pass medial to the sublingual gland, in front of and behind the hyoglossus muscle, to join the glands of the medial deep cervical group. The more *anterior* their lingual origin the *lower* in the chain is the gland to which they pass. (3) The **basal trunks**, from the posterior third of the tongue, pass from before backwards towards the inferior extremity of the tonsils, where they pierce the superior and middle constrictors of the pharynx, and, after surrounding the lingual artery, open into a gland placed on the internal jugular vein immediately below the posterior belly of the digastric. (4) The **central trunks**, which descend in the middle line between the genio-glossi, pass beneath the hyoglossus and mylo-hyoid muscles into the submaxillary space, and thence in front of the hyoid bone (having embraced the tendon of the digastric) to join the glands of the medial deep cervical group.

Between the tongue and the lingual surface of the gums is the **alveolo-glossal sulcus**, crossed in the median plane by the **frenulum linguæ**, which passes upwards to

the inferior surface of the tongue (Fig. 1065). Immediately on either side of the lower part of the frenulum is the **orifice of the submaxillary duct.** A little external to the frenulum the **profunda veins** are seen lying immediately under the thin mucous membrane; to the lateral side of the veins are the profunda arteries and the lingual nerves, both of which lie deeper than the veins, and are therefore not visible.

The mucous membrane at the anterior part of the floor of each alveolo-glossal sulcus is thrown into a slight elevation, which overlies, and is caused by, the corresponding **sublingual salivary gland.** The duct of the submaxillary gland and the lingual nerve lie beneath and to the medial side of the sublingual gland.

In dividing a shortened frenulum for "tongue-tie" the deep lingual vessels and the orifices of the submaxillary ducts must be avoided. Behind the frenulum linguæ are the anterior borders of the **genio-glossi,** which descend to the superior genial tubercles. In operations necessitating the removal of the region of the symphysis of the mandible, or the separation of the origins of the genio-glossi, the tongue must be kept forward, otherwise the patient will be suffocated by the organ falling backwards over the entrance to the larynx. In removing a small salivary calculus from the floor of the mouth the calculus should be fixed with the finger against the lingual surface of the mandible before cutting down upon it.

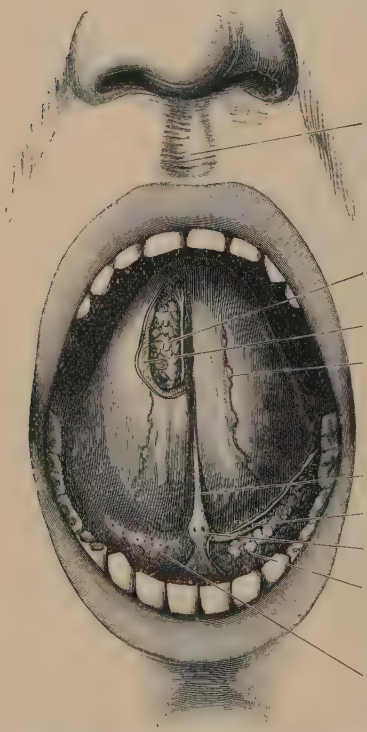

FIG. 1065.—OPEN MOUTH WITH TONGUE RAISED AND THE SUBLINGUAL AND ANTERIOR LINGUAL GLANDS EXPOSED.

The sublingual gland of the left side has been laid bare by removing the mucous membrane; to expose the anterior lingual gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the medial aspect of the gland. The profunda vein is faintly indicated on this side also. (From Birmingham.)

When the teeth are clenched the vestibule of the mouth communicates behind the last molars with the oral cavity proper through an opening which barely admits a medium-sized catheter. Hence, when the jaws cannot be separated it is generally necessary to feed the patient through a tube passed along the floor of the nose.

When the mouth is opened widely and a deep inspiration is taken, the soft palate is elevated, and the glosso-palatine and pharyngo-palatine arches are rendered prominent. The **glosso-palatine arches** spring from the anterior surface of the soft palate, close to the base of the uvula, and arch downwards and laterally, in front of the palatine tonsils, to end at the posterior end of the side of the tongue. The **pharyngo-palatine arches** are really the continuation of the lower free border of the soft palate downwards behind the palatine tonsils to become attached to, and lost upon, the side wall of the pharynx. Together with the lower edge of the soft palate and the base of the tongue they bound a hemispherical opening **(pharyngo-nasal isthmus),** through which the mucous membrane covering the posterior wall of the nasal portion of the pharynx is visible.

The **palatine tonsils** (Fig. 1066) lie one on each side of the isthmus, between the palatine arches; they are situated opposite the angle of the mandible, but they cannot be felt from the outside. Each tonsil is covered, on its free surface, by mucous membrane upon which are seen the orifices of the tonsillar crypts; the lateral or deep surface is covered by a layer of fibrous tissue which forms an imperfect capsule to the organ. According to Merkel, the internal carotid artery is situated

1·5 cm. behind the lateral margin of the tonsil, which is separated from the superior constrictor by a quantity of loose cellular tissue and fat, so that the gland can be grasped with a volsellum and pulled forwards without dragging the vessel with it. The tonsil receives its *blood-supply* mainly from a small vessel derived from the anterior palatine artery; when this branch is larger than usual and adherent to the capsule of the tonsil the bleeding which attends the operation of removal of the tonsils may be considerable. The hæmorrhage can be arrested by pressing the bleeding point outwards against the internal pterygoid and the ramus of the mandible. If the bleeding be from a spurting vessel of larger size, its source, according to Merkel, is probably the *external maxillary artery*, which has been wounded as it

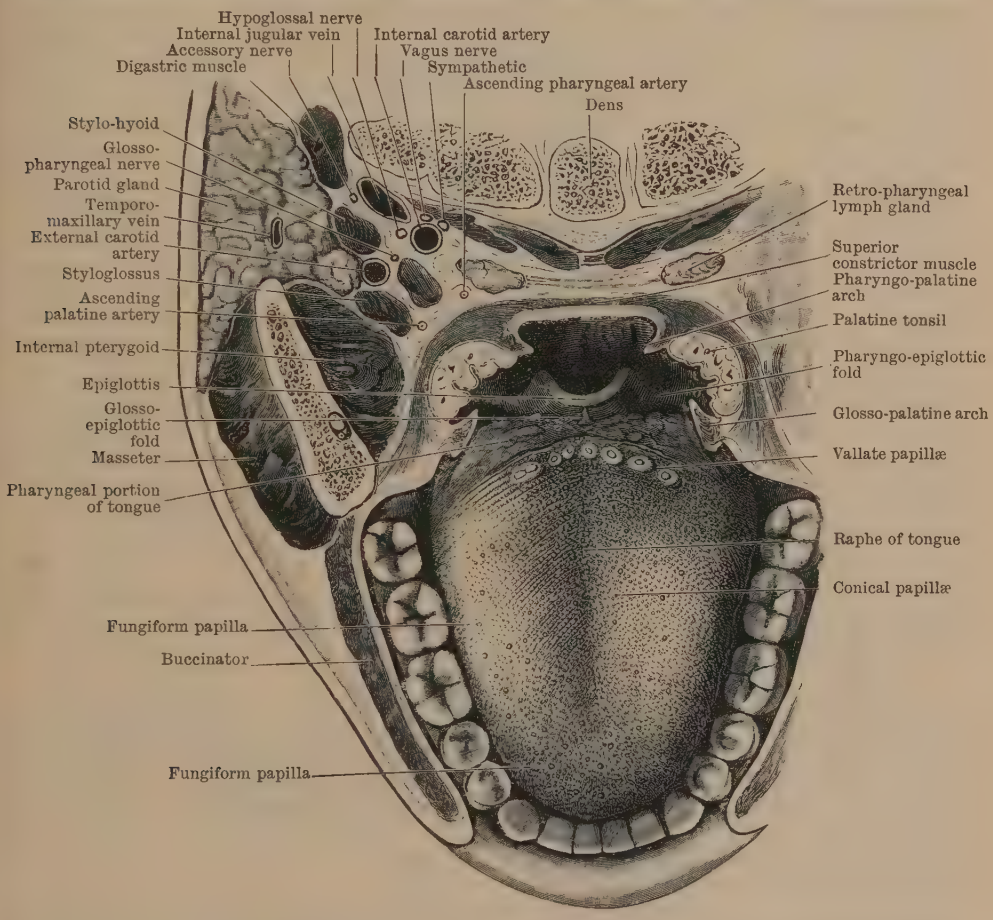

FIG. 1066.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE TONSILS.

The stylopharyngeus, which is shown immediately to the inner side of the external carotid artery, and the prevertebral muscles, are not indicated by reference lines. (From Birmingham.)

arches upwards beneath the digastric and stylo-hyoid muscles to within a short distance from the lateral surface of the tonsil. In children and adolescents the tonsils are frequently hypertrophied; the enlargement may be either general, more towards the median line, downwards along the pharynx, or upwards behind the soft palate; to expose and thoroughly remove the last-mentioned variety of enlargement the upper part of the glosso-palatine arch must be divided.

The mucous membrane and the periosteum of the **hard palate** are so closely united as to form practically one membrane. The **greater palatine arteries**, after leaving the greater palatine foramina, run forwards in shallow grooves in the hard palate, close to its alveolar margin. In the operation for cleft palate (*staphylorrhaphy*), in order to secure nourishment for the muco-periosteal flaps, the lateral incisions should be made *lateral* to those vessels.

Secondary hæmorrhage after the operation for cleft palate is treated by plugging the **greater palatine foramen**, which lies a little medial to the last molar tooth about $\frac{1}{3}$ in. in front of the hamular process, which can be felt at the superior extremity of the fold of mucous membrane containing the pterygo-maxillary ligament. In the closure of a wide cleft of the soft palate the tension of the **tensor veli palatini muscle** is got rid of by chipping off the **hamulus** with a small chisel introduced at the posterior extremity of the lateral relief incisions.

Nasal Part of the Pharynx.—To explore the superior or nasal part of the pharynx the finger should be hooked upwards behind the soft palate. *Anteriorly*, the finger readily detects the sharp posterior border of the vomer, the choanae, and the posterior extremity of the middle and inferior conchæ. The *roof* of the space is formed by the basilar part of the occipital bone, while upon the *posterior wall* is a transverse bony ridge caused by the projection of the anterior arch of the atlas. Upon the *side walls* of the nasal part of the pharynx are the openings of the **auditory tubes**, situated $\frac{1}{2}$ in. behind the posterior extremities of the inferior conchæ. The orifices, bounded superiorly and posteriorly by a prominent margin, are directed downwards and forwards, and therefore in a direction favourable to the passage of the Eustachian catheter. Behind the prominent posterior margin of the orifice is the *lateral recess of the pharynx* (O.T. **fossa of Rosenmüller**), in which the point of the Eustachian catheter is apt to become engaged. Upon the roof and posterior wall of the pharynx, down to the level of the anterior arch of the atlas, and extending laterally as far as the orifices of the auditory tubes, is a collection of adenoid tissue, the **pharyngeal tonsil**. Hypertrophy of this tissue constitutes the condition known as "*adenoids*," the harmful effects of which are due to their interference with nasal respiration. Upon the centre of the pharyngeal tonsil is an orifice leading into a small recess into which numerous mucous glands open. The structures felt in the post-nasal space may be rendered visible by reflecting the light upon a small mirror placed immediately behind and below the soft palate (*posterior rhinoscopy*). The inferior part of the inferior concha is obscured from view by the bulging of the superior surface of the soft palate.

In *plugging the posterior nares*, it is important to remember that those openings measure nearly one inch in the vertical and half an inch in the transverse direction. In the child, owing to the small size of the face, the vertical diameter of the naso-pharynx is relatively much smaller than in the adult.

The **lymph vessels** from the nasal cavities and pharynx, including the palatine and pharyngeal tonsils, join the sub-parotid and superior deep cervical glands, one of which lies medial to the carotid vessels between the lateral recess of the pharynx and the prevertebral fascia. In children suppuration originating in this gland is the commonest cause of a retro-pharyngeal abscess.

In the *adult* the four upper cervical vertebræ can be explored from the mouth, while in the *child* the finger can also reach as far down as the sixth vertebra and the back of the cricoid cartilage.

THE NECK.

The general envelope of **deep cervical fascia**, along with the processes and partitions which proceed from its deep surface, subdivides the neck into compartments which limit and determine the spread of pus. The most important compartment is the **central** or **visceral compartment**, bounded *anteriorly* by the pretracheal fascia, *posteriorly* by the prevertebral fascia, and *laterally* by the fascia forming the vascular compartment. Posteriorly, this compartment extends from the base of the skull downwards into the posterior mediastinum; anteriorly, it extends from the hyoid bone into the anterior part of the superior mediastinum. *Abscesses* in the visceral compartment are either secondary to disease of the lymph glands or organs it contains, or the result of a primary suppurative cellulitis. A tubercular abscess originating in one of the retropharyngeal lymph glands (Fig. 1066) lies *in front of* the prevertebral fascia, and points towards the posterior wall of the pharynx; abscesses secondary to disease of the cervical vertebræ lie *behind* the prevertebral

fascia, and spread laterally behind the vascular compartment; they point behind the sterno-mastoid, and should be opened through an incision at the posterior border of the muscle, the surgeon keeping to the anterior aspect of the transverse processes in order to avoid the structures in the vascular compartment (Chiene).

In front of the visceral compartment is a **small muscular compartment** containing the infra-hyoid muscles; anterior to it again, in the region of the supra-sternal notch, is the small **supra-sternal compartment**, containing the lower part of the anterior jugular veins, along with their transverse communicating branch, a little fat, and one or two lymph glands.

The vascular compartment contains the carotid vessels, and the internal jugular vein, and the following nerves, viz.: the vagus, the first part of the hypoglossal,

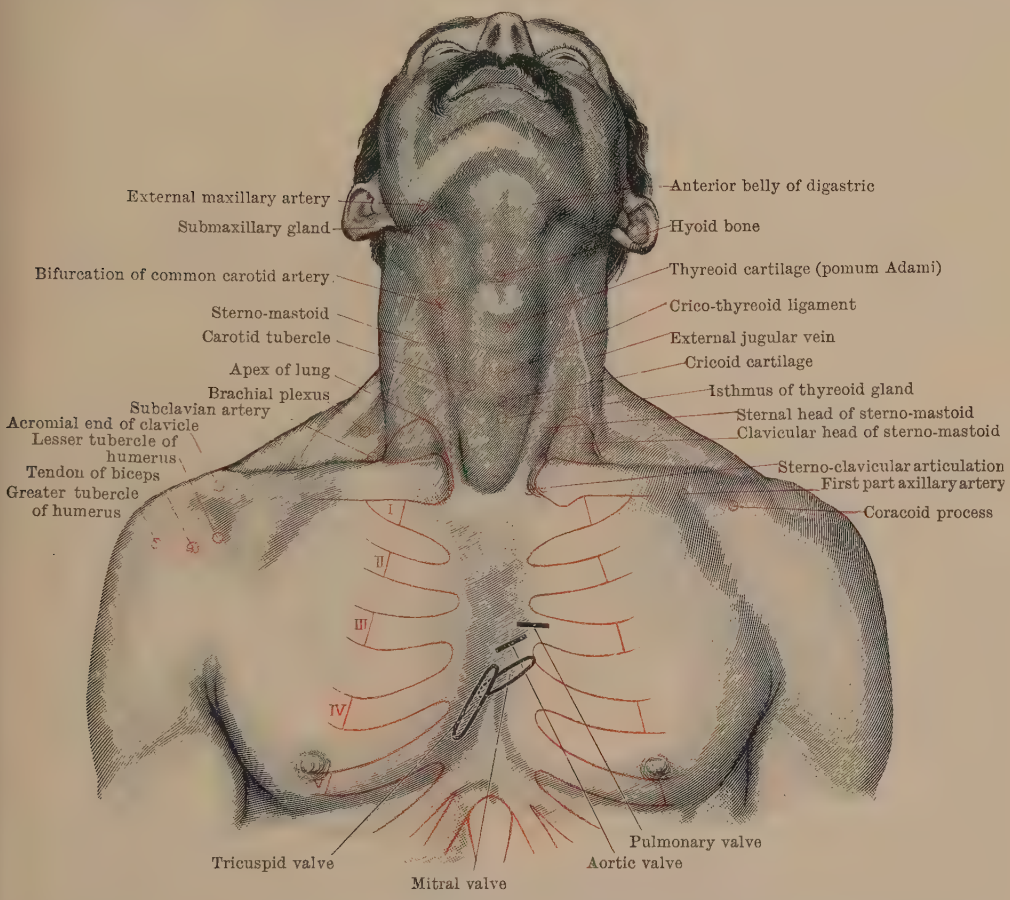

FIG. 1067.—ANTERIOR ASPECT OF NECK AND SHOULDERS.

the descendens hypoglossi, and the superior part of the accessory. These structures are enveloped in a thin fascial tube, the carotid sheath. The sheath is surrounded by cellular tissue in which are embedded the carotid chain of lymph glands; normally they may be readily separated from the sheath of the internal jugular vein, to which, however, they become adherent when inflamed. A few small lymph glands lie within the sheath. The cervical sympathetic trunk and the inferior thyreoid artery lie in the cellular space between the posterior wall of the carotid sheath and the prevertebral fascia; they can be reached through an incision along the posterior border of the sterno-mastoid muscle, this muscle, along with the carotid sheath and its contents, being pulled well forwards. In approaching the trunk of the inferior thyreoid artery from the front the sterno-mastoid and carotid sheath are retracted and the dissection is continued through the cellular interval between the carotid sheath and the sheath (outer capsule) of the thyreoid gland, which is formed by the splitting of the pretracheal fascia.

A glandular abscess in this compartment usually points upon the surface, adhesions being formed, first, between the gland and the fascia, and, subsequently, between the latter and the cutaneous structures. In diffuse suppurative cellulitis of this compartment the pus burrows towards the root of the neck, and may reach either the mediastinum or the axilla.

Median Line of the Neck.—The body of the **hyoid bone** divides the median plane of the neck into **supra-** and **infra-hyoid portions**. Above the hyoid bone is the **submental triangle**, with its apex at the inferior border of the symphysis menti and its sides formed by the anterior bellies of the digastrics. In the floor of the triangle are the anterior portions of the mylo-hyoid muscles, separated by the median raphe (Fig. 1068). The most important structures in the triangle are the **submental lymph glands**, which can usually be felt a little above the body of the hyoid bone. In children they are a frequent seat of abscess secondary to impetigo of the lower lip and chin. About 1 in. below the hyoid bone is the **pomum Adami**, more prominent in the male than in the female. On either side of the pomum Adami

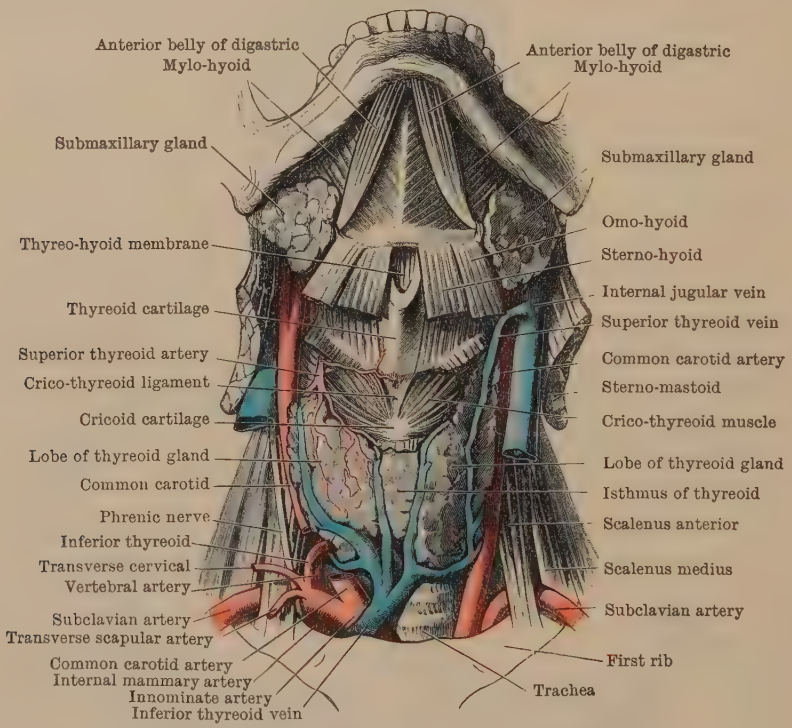

FIG. 1068.—DISSECTION OF THE FRONT OF THE NECK. The lower portions of the sterno-mastoid muscles have been removed, and the lower part of the right common carotid artery cut away to show the deeper parts. (From Cunningham.)

are the laminæ of the thyreoid cartilage, while between the latter and the hyoid bone is the **thyreo-hyoid membrane**. In the operation of *sub-hyoid pharyngotomy* the epiglottis and the superior opening of the larynx are reached by passing through the anterior wall of the pharynx at the level of the thyreo-hyoid membrane. The structures divided from without inwards are: the integuments, the sterno-hyoid, omo-hyoid, and thyreo-hyoid muscles, the median portion of the thyreo-hyoid membrane, along with a layer of fat between it and the lower part of the epiglottis, and, finally, the glosso-epiglottic ligament and fold of mucous membrane. The incision must not be extended too far on either side of the median plane for fear of wounding the **superior laryngeal vessels** and **nerve** which pierce the thin lateral portions of the thyreo-hyoid membrane.

The wound in suicidal *cut-throat* is generally at this level. The more important structures which are usually divided are: more or less of the left sterno-mastoid muscle, the superior thyreoid vessels, the thyreo-hyoid membrane, the base of the epiglottis, and, less frequently, the carotid vessels, the internal jugular vein, and the superior laryngeal nerve. When the wound is above the hyoid bone, the lingual and external maxillary vessels and the muscles of the tongue are the more important structures injured.

At the level of the middle of the anterior border of the thyreoid cartilage is the **rima glottidis.**

In the operation of thyreotomy care is taken to divide the thyreoid cartilage exactly in the median plane so as to avoid injuring the vocal folds.

A little more than an inch below the prominentia laryngea is the anterior arch of the **cricoid cartilage**, which may be readily felt, and, when the neck is extended, often seen; it lies a little below a point midway between the lower margin of the chin and the superior border of the sternum. Above the cricoid is the **crico-thyreoid ligament**; in the operation of laryngotomy only the middle portion of the ligament is divided, in order to avoid injury to the crico-thyreoid muscles. The small crico-thyreoid branch of the superior thyreoid artery lies close to the inferior border of the thyreoid cartilage. Below the cricoid cartilage is the **trachea**, which recedes as it descends, so that it lies 1½ in. from the surface at the level of the superior border of the sternum. The **isthmus** of the **thyreoid gland** lies in front of the second, third, and fourth rings of the trachea (Fig. 1068); not infrequently, however, it reaches up to the cricoid. Immediately in front of the trachea, below the isthmus of the thyreoid, is the pretracheal fat, containing one or two **lymph glands** and the **inferior thyreoid veins**, each represented by one or more branches which converge as they descend. The pretracheal lymph glands receive afferent vessels from the larynx and thyreoid gland, while their efferent vessels open into the inferior deep cervical glands. In the adult the **innominate artery** crosses the front of the trachea at the level of the superior border of the sternum; in the child, however, it not infrequently crosses half an inch higher, a relation which must be remembered in performing the operation of low tracheotomy.

In the operation of **high tracheotomy** the upper three rings of the trachea are divided. The incision, which should be median, divides the integuments, the tributaries of the anterior jugular veins, the general envelope of deep cervical fascia, and, after passing between the depressor muscles of the hyoid bone, the pretracheal fascia, which descends from the cricoid to enclose the isthmus of the thyreoid gland. By dividing this fascia transversely below the cricoid, the isthmus may be pulled downwards and the upper rings of the trachea exposed. In some cases it is necessary either to divide the isthmus or to extend the incision upwards through the cricoid cartilage. In opening the trachea, the edge of the knife should be directed upwards so as to avoid injuring the vessels at the upper border of the isthmus. The anterior jugular veins are in danger of being wounded if the skin incision is not strictly median. In low tracheotomy the trachea below the isthmus is opened; it is a more troublesome operation, on account of the depth of the trachea and the presence in front of it of the large inferior thyreoid veins and of the transverse anterior jugular vein. In children the difficulty is increased by the higher position of the innominate artery and left innominate vein, by the presence of the thymus gland, and by the shortness of the neck.

Thyreoid Gland.—The thyreoid gland, which is moulded on and adherent to the anterior aspects and the sides of the upper part of the trachea and to the lower and posterior portions of the laminæ of the thyreoid cartilage, is covered by the infrahyoid muscles and overlapped by the sterno-mastoid. The posterior borders of its lobes come in contact with the œsophagus and lower part of the pharynx, while posteriorly they partially overlap the carotid sheath.

The thyreoid gland, like the prostate, possesses, in addition to its own proper capsule, an outer capsule or sheath derived from the cervical fascia. The capsule proper, like that of the liver, is inseparably connected with the gland. The sheath, on the other hand, is formed by the middle (pretracheal) layer of deep cervical fascia, which splits to enclose the thyreoid. Between the true capsule and the sheath is a loose cellular interval which is crossed by branches of the thyreoid arteries and veins on their way to and from the gland. The arteries traverse the space directly, while many of the veins (accessory thyreoid veins of Kocher) ramify for some distance on the surface of the capsule before they pierce the sheath.

The surgeon reaches the gland through the median plane in the interval between the infrahyoid muscles. If, in order to obtain more room, it is found necessary to divide the depressor muscles on one or both sides, this should be done towards their upper attachments, as their nerves of supply, derived from the ansa hypoglossi, enter the muscles nearer their lower attachments.

By freely dividing the middle layer of cervical fascia where it forms the anterior portion of the sheath of the thyreoid, the gland can be delivered out of the wound and so mobilised that the main vessels may be brought into view and ligatured.

The superior thyreoid vessels, on each side, are exposed by freeing and drawing forwards the superior pole of the corresponding lobe. The inferior thyreoid artery is sometimes ligatured as a preliminary step to operating on the thyreoid gland. In this event the ligature is applied to the trunk of the vessel as it lies behind the carotid sheath in the cellular space between it and the prevertebral fascia (De Quervain). In the operation of partial thyreoidectomy the posterior part of the true capsule of the gland and a layer of thyreoid substance are left behind so as to guard against injury to the parathyreoids and the recurrent laryngeal nerve. In this procedure the branches of the inferior thyreoid artery are ligatured after they have pierced the true capsule of the gland. The recurrent nerve, which also lies between the posterior part of the sheath and the postero-medial aspect of the corresponding lobe, ascends, either posterior to the inferior thyreoid artery or between its main divisions.

The parathyreoids can generally be distinguished from the thyreoid tissue itself, and from the lymph glands, by their grayish-yellow colour as well as by their smooth and shining surfaces. The superior parathyreoid is found on each side usually, one at the posterior border of the corresponding lobes, about opposite the cricoid cartilage. It is in close relation to the pharyngo-œsophageal junction, from which it is separated by the posterior part of the sheath of the thyreoid

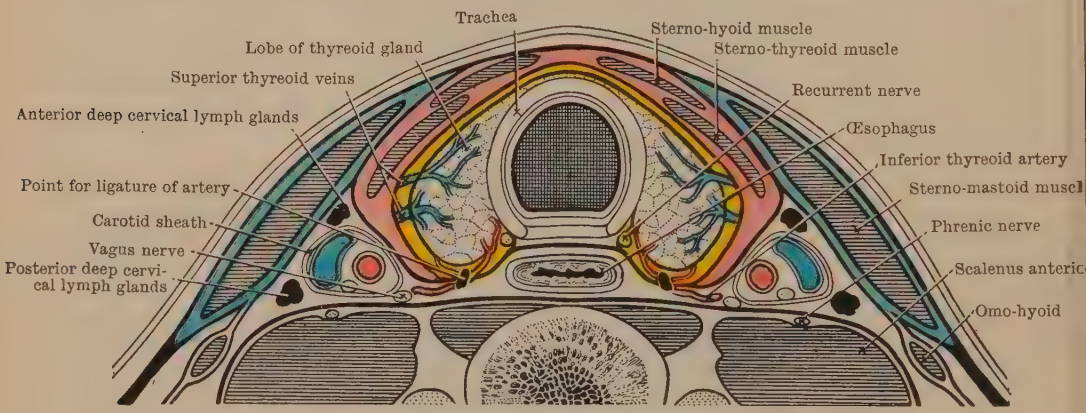

Fig. 1069.—A Diagram of the Relations of the Cervical Fascia to the Thyreoid Gland.

Blue = deep cervical fascia (sterno-mastoid layer). Red = outer capsule of thyreoid gland (pretracheal layer of cervical fascia). Yellow = capsule proper of the thyreoid gland. (Modified from De Quervain.)

gland. The inferior parathyreoid gland, on each side, is supplied by a small vessel from one of the branches of the inferior thyreoid artery; it occupies the same cellular interval at the posterior aspect of the inferior pole of the gland, a little lateral to the inferior thyreoid artery and the recurrent nerve. When the inferior thyreoid artery has been ligatured the posterior branch of the superior thyreoid artery furnishes a sufficient blood-supply to the inferior parathyreoid gland.

Triangles of the Neck.—The lateral aspect of the neck is divided into an **anterior** and a **posterior triangle** by the sterno-mastoid muscle; the former is further subdivided into *digastric*, *carotid*, and *muscular triangles* by the digastric and omo-hyoid muscles. The posterior triangle is subdivided into *occipital* and *subclavian portions* by the posterior belly of the omo-hyoid.

The **sterno-mastoid muscle** forms one of the most important superficial landmarks of the neck. The anterior border of the muscle, the more distinct of the two, may be felt along its whole extent. Between the prominent sternal origin and the broad ribbon-like clavicular origin is a slight triangular depression which overlies the inferior part of the internal jugular vein.

By dividing the cervical fascia along the anterior and posterior borders of the muscle the surgeon is able to displace the muscle backwards and forwards so as to obtain free access to the structures deep to it. If the posterior fibres of the muscle are divided at their clavicular and mastoid attachments the muscle can be still more freely mobilised. In dividing the fascia along its posterior border the cutaneous branches of the cervical plexus are generally divided, but care

is taken not to injure the accessory nerve. Should it be found necessary to remove the upper third or more of the muscle, the divided end is stitched to the levator scapulæ or to the scalenus medius, according to the amount resected. In dividing the muscle completely across at the lower part of the neck, as is done, for example, in congenital wry-neck, the close relation of the anterior and external jugular veins to its corresponding borders must be kept in mind. After division of the muscle, the lower part of the anterior belly of the omo-hyoid is seen, lying upon that part of the carotid sheath which overlies the internal jugular vein.

Digastric Triangle.—This triangle is subdivided into an anterior or submaxillary portion and a posterior or parotid portion by a process of the deep cervical fascia, known as the stylo-mandibular ligament. In the anterior portion is the **submaxillary gland**, which is overlapped by the posterior half of the inferior border of the mandible and reaches down to the great cornu of the hyoid bone. The **anterior facial vein** passes downwards and backwards, superficial to the gland, while the **external maxillary artery**, embedded in its deep surface, arches

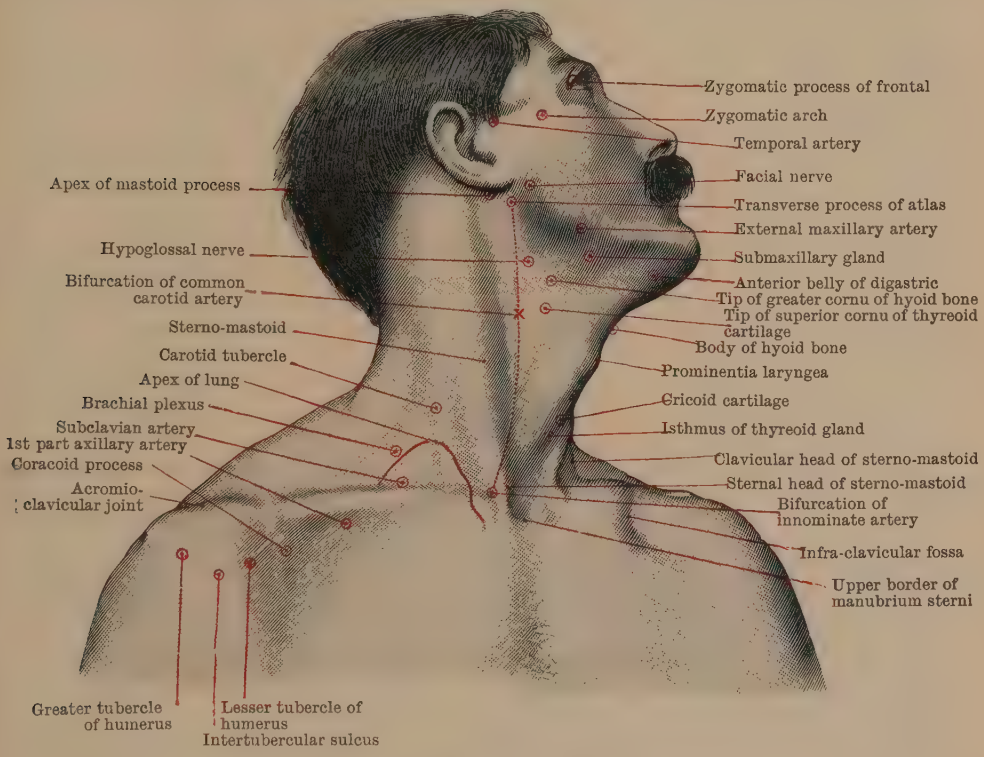

Fig. 1070.—Side of the Neck.

upwards under cover of the angle of the mandible, where it approaches the palatine tonsil, being separated from it, however, by the superior constrictor of the pharynx. The **lingual artery** may be ligatured in the digastric triangle, where it lies behind the hyoglossus a little above the great cornu of the hyoid bone; the superficial guides to the vessel are the inferior border of the submaxillary gland, and the hypoglossal nerve and its vena comitans, which lie upon the hyoglossus, the latter being recognised by the vertical direction of its fibres. The *floor* of the digastric triangle is formed, from before backwards, by the mylo-hyoid, hyoglossus, and superior constrictor of the pharynx. The **lymph glands** of this space receive their lymph from the face, lips, teeth and gums, tongue, and floor of the mouth; hence the frequency with which they become the seat of abscess formation and malignant enlargement. To palpate them the surgeon stands behind the patient and thrusts the fingers well upwards under cover of the mandible, the patient's chin being a little depressed so as to relax the cervical fascia.

Carotid Triangle.—The central landmark of this triangle is the **great cornu** of the **hyoid bone**, the tip of which, when the fascia is relaxed, may be readily felt,

immediately in front of the anterior border of the sterno-mastoid, at a point corresponding to the centre of a line drawn from the tip of the mastoid process to the prominentia laryngea. The deep cervical fascia holds the superior part of the sterno-mastoid forwards towards the angle of the mandible, so that, with the fascia undivided, the anterior border of the sterno-mastoid overlaps the internal jugular vein and the bifurcation of the common carotid artery.

The **course of the carotid vessels** is indicated, upon the surface, by a line extending from the superior end of the sterno-clavicular articulation to a point midway between the angle of the mandible and the tip of the mastoid process; a point upon this line, at the level of the superior border of the thyreoid cartilage, overlies the **bifurcation of the common carotid**. The **anterior belly** of the **omo-hyoid** crosses the common carotid at the level of the cricoid cartilage. The pulsations of the carotid vessels may be felt in the hollow between the larynx and the anterior border of the sterno-mastoid. In the carotid triangle the **external carotid** lies medial and anterior to the internal carotid. The seat of election for *ligation of the external carotid* is between its superior thyreoid and lingual branches, a finger's-breadth below the tip of the great cornu of the hyoid bone; the difficulty in the operation is due to the plexus of veins (formed by the common facial, lingual, and superior thyreoid veins) which overlies the artery. The lingual and external maxillary arteries frequently arise from a common trunk which must not be mistaken for the external carotid. The **superior thyreoid artery** arises opposite the upper cornu of the thyreoid cartilage, which may be distinctly felt 1 in. below the tip of the great cornu of the hyoid bone. The vessel and its companion vein are common sources of hæmorrhage in cut-throat. The guide to the **lingual artery**, in the carotid triangle, is the tip of the great cornu of the hyoid bone, above which it forms an arch, crossed by the hypoglossal nerve. The vessel enters the digastric triangle by passing forward medial to the tendons of the stylo-hyoid and digastric muscles. When ligature of the artery is called for, it is usually necessary to secure the vessel as it lies in the carotid triangle so that the ligature may be applied on the proximal side of its dorsalis linguæ branch.

From a surgical point of view the **internal jugular vein** is the most important structure in the anterior triangle. In the carotid division of the triangle it overlaps the carotid vessels, and its sheath lies close beneath the general envelope of deep cervical fascia from which it is separated by a loose cellular interval. About the level of the hyoid bone it receives the large common facial vein, while at an inferior level it receives the superior and middle thyreoid veins which are often greatly enlarged in goitres.

By the term **deep cervical glands** is included a broad chain of lymph glands which is closely related to the internal jugular vein, and which stretches from the transverse process of the atlas to the root of the neck. The chain is in reality made up of subsidiary glandular groups, each of which receives its lymph vessels from fairly well-defined areas. In the first place, the chain may be divided into an upper and a lower portion, the former situated above the bifurcation of the common carotid artery, the latter below it. Each of these divisions is again subdivided into a medial and a lateral chain.

Of the four groups, the *superior medial* is the most important, as it is there that disease first manifests itself in the vast majority of cases. The reason for this predilection is the fact that this group of glands, in addition to receiving efferent lymph vessels from the glands of the circular chain, receives also lymph vessels directly from the nasal part of the pharynx, including the palatine and pharyngeal tonsils. These latter structures are now known to provide the chief portals of entrance through which the tubercle bacilli reach the efferent lymph vessels. Wood, of Philadelphia, has succeeded in tracing the lymph vessels from the palatine tonsils directly into one of the glands of this group, namely, that situated a little below the angle of the mandible, under cover of the anterior border of the sterno-mastoid immediately below the posterior belly of the digastric. The relations of the deep surface of this gland are important. It lies upon the anterior surface of the internal jugular, in the angle between it and the common facial vein. It plays such an important rôle in tuberculous adenitis that it is now termed by surgeons

the *tonsillar lymph gland.* In the great majority of cases it is the first gland in the neck to show signs of tuberculous enlargement. When the superior medial deep cervical glands become enlarged they form a swelling which projects from beneath the sterno-mastoid forwards into the carotid division of the anterior triangle. The mass soon becomes adherent to the general envelope of deep cervical fascia, and, if the disease is allowed to run its course, the latter becomes perforated, with the result that a subcutaneous tuberculous abscess soon develops. The glands are also liable to become adherent to the digastric muscle, and to the stylo-mandibular ligament, which separates them from the submaxillary lymph glands. The most important adhesions, however, from the surgeon's point of view, are to the common facial and internal jugular veins.

The *superior lateral* group of deep cervical glands lies postero-lateral to the internal jugular upon the origins of the splenius and the levator scapulæ muscles. They are smaller in size than the medial group, but when enlarged they may form a swelling which projects across the posterior triangle as far as the trapezius. They are embedded in a quantity of fibro-fatty tissue which supports the accessory nerve and the cervical plexus. Wood has shown that the lymph vessels from the pharyngeal tonsil, after piercing the posterior wall of the pharynx, pass downwards and laterally behind the sheath of the great vessels to enter the glands situated deeply, just below the tip of the mastoid process.

The *inferior medial* group forms a somewhat narrow chain, which is continued down the anterior aspect of the internal jugular as far as its junction with the subclavian. Above the bifurcation of the common carotid artery this chain is continuous with the superior medial jugular group, while, below, it comes into relation with the superior mediastinal glands.

The *inferior lateral* group of deep cervical glands is continuous above with the superior lateral group. Like the superior lateral group, they lie altogether behind the internal jugular vein, upon the levator scapulæ, the scalenus medius, and the brachial plexus. The most inferior glands of the group, viz., the supra-clavicular, are subdivided into a superficial and a deep cluster by the omo-hyoid muscle and the middle layer of deep cervical fascia. They receive their afferent vessels from the subclavicular group of axillary glands.

The **hypoglossal nerve** is deeply placed in the carotid triangle, being overlapped by the internal jugular vein and the inferior border of the posterior belly of the digastric muscle. It crosses forwards, superficial to the occipital and internal and external carotid arteries, immediately below the origin of the superior sterno-mastoid branch of the first-mentioned vessel. The **vagus nerve** descends vertically, within the carotid sheath, behind and between the carotid vessels and the internal jugular vein; care must be taken not to include it when ligaturing the common carotid or internal jugular. Surgically, the **accessory** is the most important nerve in the anterior triangle; it enters the substance of the sterno-mastoid muscle $1\frac{1}{2}$ in. below the tip of the mastoid process. A portion of the nerve is resected in the treatment of spasmodic wry-neck, and it is always exposed in the removal of the medial group of deep cervical glands. The course of the nerve may be mapped out upon the surface by drawing a line from a point midway between the tip of the mastoid process and the angle of the mandible to a little above the middle of the posterior border of the sterno-mastoid muscle, and thence across the posterior triangle to the junction of the middle and lower thirds of the anterior border of the trapezius, beneath which it passes at the level of the seventh cervical spine. The deeper guides to the nerve are the posterior belly of the digastric, and the internal jugular vein which it crosses, very obliquely, from above downwards and backwards below and in front of the **transverse process of the atlas** (felt as a distinct bony landmark midway between the tip of the mastoid and the angle of the mandible).

In paralysis of the trapezius muscle from injury to the accessory nerve the shoulder droops and is pulled forwards and medially by the pectoralis major and minor muscles. If the paralysis occurs during childhood the chest on the same side becomes flattened anteriorly, due to the adaptive shortening of the pectorals and to their diminished pull on the ribs. Unless this

mechanism is appreciated the infra-clavicular flattening of the chest is very apt to be erroneously attributed to pulmonary tuberculosis. The upper part of the accessory nerve is surrounded by the superior lateral group of deep cervical glands; it is in this situation, and again when it emerges from beneath the posterior border of the sterno-cleido-mastoid muscle, that it is liable to be injured in operations for the removal of tuberculous glands.

The **cervical sympathetic** lies in the posterior wall of the vascular compartment of the neck, and may be reached by an incision along the posterior border of the sterno-mastoid: the anterior surfaces of the roots of the transverse processes of the vertebræ are the deep guides to the nerve.

The **cervical plexus**, which lies deep to the superior half of the sterno-mastoid upon the levator scapulæ and scalenus medius muscles, may be exposed through an incision along the posterior border of the upper half of the sterno-mastoid muscle. The **phrenic nerve**, the most important branch of the cervical plexus, arises one inch above the carotid tubercle and descends almost vertically towards the inner end of the clavicle; it is overlapped by the lateral margin of the internal jugular vein. Although frequently exposed by the surgeon in removing the lower medial group of deep cervical glands, the phrenic nerve is protected from injury by the prevertebral fascia which binds it down to the scalenus anterior muscle.

The **muscular** or **lower carotid triangle** is an important triangular intermuscular space bounded by the anterior border of the sterno-mastoid, the anterior belly of the omo-hyoid, and the sterno-hyoid. Behind this space, and forming, as it were, its floor, is a still deeper space bounded by the longus colli and scalenus anterior muscles. It may with advantage be termed the *prevertebral intermuscular triangle*, or, from the fact that it contains the vertebral artery, it may be termed the *vertebral arterial triangle*. At its apex is the prominent anterior tubercle of the transverse process of the sixth cervical vertebra. By making an incision along the anterior border of the left sterno-mastoid muscle, and passing through this triangle, the surgeon reaches, in order from before backwards, the internal jugular vein, the common carotid artery, the vagus, the thoracic duct, the middle cervical ganglion of the sympathetic, the inferior thyreoid artery, the vertebral vessels, the recurrent nerve, and the œsophagus. The most important bony landmark in this triangle is the prominent anterior tubercle of the transverse process of the sixth cervical vertebra. The common carotid artery may be compressed against this tubercle, which is therefore termed the "*carotid tubercle*." It is the most important guide to the vertebral artery, which enters the foramen in the transverse process of the sixth cervical vertebra.

The **cervical portion** of the **œsophagus**, which begins at the level of the cricoid cartilage, descends behind, and a little to the left of, the trachea. To expose it, the surgeon, after passing through the above-mentioned muscular triangle, divides the pretracheal fascia, and passes between the trachea and the carotid sheath down to the longus colli muscle medial to the inferior thyreoid artery and vertebral vessels. The lower pole of the corresponding lobe of the thyreoid gland is retracted medially along with the trachea. The œsophagus lies in the loose cellular tissue in front of the prevertebral fascia; hence it can be mobilised sufficiently to admit of its being brought to the surface. The œsophagus may also be exposed through an incision in the median plane, the trachea, which is freely movable, being displaced to the right side. In opening the œsophagus care must be taken not to injure the **recurrent nerve**, which ascends in the groove between it and the trachea, and also that the loose submucous cellular interval must not be mistaken for the lumen of the tube. The so-called "pulsion-diverticulum of the œsophagus" does not take origin from the upper part of the gullet, as frequently stated; it begins as a hernia-like protrusion of the posterior wall of the pharynx, between the oblique thyreo-pharyngeal and the transverse crico-pharyngeal fibres of the inferior constrictor muscle (Killian). During the act of swallowing the latter fibres act as a sphincter, while the oblique fibres elevate the larynx. If the sphincter should fail to relax during the detrusor action of the pharynx it is not difficult to understand how a diverticulum might arise, and, when once produced, why it should undergo progressive enlargement.

The Thoracic Duct.

The **thoracic duct**, after entering the root of the neck between the œsophagus and the pleura, ascends to about an inch above the clavicle. At this level it arches laterally behind the lower part of the carotid sheath in front of the vertebral vessels. Great care must therefore be taken not to injure the duct in removing the lymph glands which lie in the loose cellular tissue behind the inferior part of the internal jugular vein, between it and the vertebral vein at the medial border of the scalenus anterior. In addition to those glands a few small lymph glands lie adjacent to the lateral aspects of the cervical portions of the trachea and œsophagus. They receive their afferent vessels from the larynx, trachea, œsophagus, and thyreoid gland.

Posterior Triangle.

The roof of the posterior triangle is formed by the general envelope of deep cervical fascia, while the fascia which covers the muscles forming its floor, as well as that covering the brachial nerve trunks and the subclavian artery, is a lateral continuation of the prevertebral fascia. The lateral deep cervical and supra-clavicular lymph glands are embedded in the cellular tissue between these two layers of fascia. In removing these glands, every endeavour should be made to preserve the motor nerves. The accessory nerve, after entering the posterior triangle at the junction of the superior and middle thirds of the posterior border of the sterno-mastoid muscle, crosses the triangle superficially, and parallel to the levator scapulæ. It leaves the triangle by passing under cover of the anterior border of the trapezius, at the junction of its middle and inferior thirds. The lesser occipital nerve curves round the accessory from below upwards, superficially, just at the posterior border of the muscle; it furnishes, therefore, a useful guide to the position of that important motor nerve.

The **dorsalis scapulæ nerve** (O.T. **nerve to the rhomboids**) crosses the triangle, inferior to the accessory, and enters the septum between the levator scapulæ and scalenus medius muscles.

The **supra-scapular nerve** is seen arising from the lateral edge of the upper trunk of the brachial plexus, a little above the posterior belly of the omo-hyoid muscle. The loops of the cervical plexus lie under cover of the upper part of the sterno-mastoid muscle, between it and the origins of the levator scapulæ and the upper part of the scalenus medius muscles.

The posterior belly of the omo-hyoid, which forms the superior boundary of the **subclavian division** of the posterior triangle, passes beneath the posterior border of the sterno-mastoid at a point about one inch above the clavicle. The **external jugular vein**, usually visible through the skin, runs in a line from the angle of the jaw to the middle of the clavicle; it is the vessel which is generally opened to relieve the right side of the heart in asphyxia. The lumen of the vein is kept patent where it pierces the fascia of the subclavian triangle; hence a wound of the vein in that situation is liable to be followed by the suction of air into the circulation during inspiration. The **third part** of the **subclavian artery** can be compressed against the first rib by pressing downwards and backwards, immediately above the clavicle, a little behind the posterior border of the sterno-mastoid muscle. To map out the *course* of the subclavian artery in the neck, draw a line, convex upwards, from the superior border of the sterno-clavicular articulation to the middle of the clavicle, the highest part of the arch to reach from $\frac{1}{2}$ to 1 in. above the bone.

To *ligature the vessel* in the third part of its course, an angular incision is made along the middle of the superior border of the clavicle and the inferior part of the posterior border of the sterno-mastoid muscle. The most important guides to the vessel are the posterior belly of the omo-hyoid, the lateral border of the scalenus anterior, and the scalene tubercle of the first rib. The close relation of the vessel to the lowest trunk of the brachial plexus and to the cervical pleura must be kept in mind. In the rare instances in which a cervical rib is present the subclavian artery lies either in front of it, or arches above it, according to the degree of development of the rib. The **subclavian vein** lies below, and anterior to, the artery, altogether under cover of the clavicle.

Entering the posterior triangle, from behind the lateral border of the scalenus anterior, are the trunks of the **brachial plexus**. They lie upon the scalenus medius, and can be felt, through the skin, immediately above and behind the third part of the subclavian artery. The anterior ramus of the fifth cervical nerve supplies the rhomboids, the abductors and lateral rotators of the arm, and the flexors and supinators of the forearm; that of the sixth the serratus anterior, the adductors and medial rotators of the arm, and the extensors and pronators of the forearm; that of the seventh the flexors and extensors of the wrist; that of the eighth the flexors and extensors of the fingers; that of the first thoracic the small muscles of the hand. Each root of the brachial plexus contributes to the nerve supply of the pectoralis major muscle, and as the fibres of the muscle are supplied from above downwards by the roots in their numerical order, valuable information is obtained by carefully testing the action of the muscle in all suspected cases of injury to the brachial plexus.

When the first thoracic root is ruptured within or close to the spinal canal, the sympathetic fibres which run in it on their way to join the inferior cervical ganglion of the sympathetic are torn across, with the result that, among other symptoms, there will be (1) contraction of the pupil, due to paralysis of the radial fibres of the iris; (2) narrowing of the palpebral fissure, due to paralysis of the involuntary fibres of the upper eyelid; (3) slight recession of the eyeball (enophthalmos), due to paralysis of the non-striated orbital muscle of Müller.

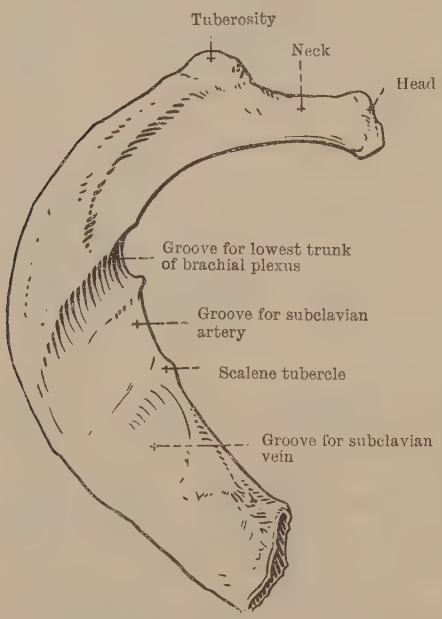

Fig. 1071.—The First Rib, seen from Above.

As regards the cutaneous root distribution of the upper limb, the sensory fibres from the lateral (pre-axial) border of the upper arm enter the fifth root, while those from the lateral half of the forearm and hand enter the sixth root. The sensory fibres from the medial (post-axial) part of the hand enter the eighth cervical nerve, those from the medial border of the forearm enter the first thoracic, while those from the medial aspect of the upper arm run in the second thoracic nerve. The carotid tubercle lies between the anterior rami of the sixth and seventh cervical nerves. The fifth and sixth cervical nerves are those which suffer most when the plexus is injured by forcible depression of the shoulder while the head is bent to the opposite side, such as occurs, for instance, in the "Obstetrical Paralyses" of Duchenne. The lowest trunk is most liable to be overstretched when traction is applied either to the upper limb or to the trunk when the former is elevated above the shoulder.

To expose the trunks of the brachial plexus an incision is made from the junction of the middle and inferior thirds of the posterior border of the sterno-mastoid downwards and laterally to the junction of the lateral and intermediate thirds of the clavicle.

The relation of the lowest trunk of the brachial plexus to the first rib is important in relation to those forms of brachial neuritis in which the motor and sensory symptoms indicate pressure on the anterior ramus of the first thoracic nerve. Wood Jones has shown that the sulcus for the subclavian artery on the superior surface of the first rib lodges the lowest trunk of the brachial plexus as well as the artery, and that the more the first and second thoracic nerves contribute to the plexus, that is to say the more "caudal" the plexus (*vide* p. 1387), the deeper is the sulcus.

In 175 dissections of the brachial plexus Abram Kerr found the cephalic type

in 62 per cent, the so-called "normal" type in 30 per cent, and the caudal type in 8 per cent. In the cephalic type the fourth cervical nerve sends a branch to the plexus; in the "normal" type the fourth cervical contributes no branch; in the caudal type while only a part of the fifth cervical joins the plexus a large contribution is derived from the first thoracic, and frequently a branch also from the second thoracic.

In several cases the writer has cured the neuralgia and the partial paralysis of the intrinsic muscles of the hand supplied by the first thoracic nerve by removing the portion of the first rib containing the "sulcus nervi brachialis." The symptoms were due to the portion of the first thoracic nerve which goes to join the brachial plexus being stretched and pressed upon by the first rib as it crosses its inner edge to join the eighth cervical nerve. Although similar symptoms may be produced by the first thoracic nerve being stretched across a cervical rib, the surgeon must not expect to find this anomaly in all cases; and when a skiagram has been obtained, care must be taken not to mistake a well-developed posterior tubercle of the transverse process of the seventh cervical vertebra for a foreshortened view of a rudimentary cervical rib.

In cases in which the first rib produces neuritis from pressure on the first thoracic nerve, it is necessary to remove the portion of the bone between its tubercle and the scalene tubercle. In order to expose and detach the scalenus medius muscle from its insertion into this part of the rib the plexus must be freed from the anterior surface of this muscle and then retracted downwards and medially. In doing this, care must be taken not to injure either of the roots of the posterior thoracic nerve which pierce the muscle or the trunk of the nerve; the latter descends behind the lateral edge of the plexus and then crosses the upper digitation of the serratus anterior to enter the axilla. This muscle and the muscles of the first intercostal space are detached from the outer border of the rib, while Sibson's fascia is separated from the inner border of the rib, and in doing this care must be taken not to injure the pleura.

In the median line of the neck posteriorly is the **nuchal furrow**, at the bottom of which are the cervical spines and the ligamentum nuchæ. At the superior part of the furrow, about two inches below the external occipital protuberance, is the large **spine of the epistropheus**, which can be distinctly felt; a line drawn from it laterally and slightly upwards to the transverse process of the atlas corresponds to the position of the inferior oblique muscle and, therefore, to the inferior margin of the **sub-occipital triangle**. The course of the deep part of the **greater occipital nerve** may be mapped out by drawing a line from the centre of the above-mentioned line to a point one inch lateral to the external occipital protuberance. In the floor of the sub-occipital triangle is the posterior arch of the atlas upon which the **vertebral artery** lies.

THE THORAX.

For the convenience of topographical description, clinicians, by the use of vertical and transverse lines, have arbitrarily divided the surface of the chest into certain definite regions or areas. The vertical lines are: the *mid-sternal*, the *lateral sternal*, the *para-sternal*, the *mammary* or *mid-clavicular*, the *anterior*, *mid*, and *posterior axillary*, and the *scapular*. The position of the mid- and lateral sternal lines is sufficiently indicated by their names.

The **mammary**, better termed the **mid-clavicular**, is drawn vertically downwards from the centre of the clavicle, or, what comes to practically the same thing, from a point midway between the centre of the jugular notch and the tip of the acromion. In the male this line usually lies $\frac{1}{2}$ to $\frac{3}{4}$ in. medial to the centre of the nipple, which is usually placed over the fourth interspace, or fifth rib, four inches from the median plane. In the child the nipple may be as high as the inferior border of the third rib. In the female the position of the nipple is so variable that it is of no topographical value. In a well-proportioned subject, the mid-clavicular line, if prolonged downwards, will be found to be continuous with the vertical or lateral inguinal line, which crosses the costal margin at the tip of the ninth costal cartilage.

The **para-sternal line**, drawn midway between the lateral sternal and mid-clavicular, crosses the costal margin opposite the tip of the eighth costal cartilage.

The **anterior**, the **mid**, and the **posterior axillary lines** are drawn downwards from the anterior fold, the apex, and the posterior fold of the axilla, respectively.

The **scapular line** is drawn perpendicularly through the inferior angle of the scapula.

Of the *two transverse lines*, the **superior**, which separates the **infra-clavicular** and **supra-sternal** regions from the **mammary** and **infra-sternal** regions, is drawn at the level of the third chondro-sternal articulation; the **inferior**, which separates the **mammary** and **infra-mammary** regions, is drawn at the level of the sixth chondro-sternal articulation.

The lateral area of the chest is divided into a superior, or **axillary**, and an inferior or **infra-axillary** region, by a horizontal line drawn at the level of the sixth rib.

In muscular subjects there is a well-marked median furrow, the **sternal furrow**, between the sternal origins of the **pectoralis major muscles**. The medial part of the inferior border of each of these muscles forms a curved prominence which, overlying the fifth rib, corresponds to the junction of the mammary and infra-mammary regions. Below this prominence is the infra-mammary region, which forms a somewhat flat surface, corresponding to the upper part of the rectus muscle. In the axillary and infra-axillary regions are the prominences caused by the digitations of origin of the **serratus anterior**, the first to appear below the pectoralis major being that which springs from the fifth rib.

The **superior border** of the **sternum** lies in the same horizontal plane as the inferior border of the body of the second thoracic vertebra, the distance between the two being about two inches. The junction of the manubrium and the body of the sternum forms a slight prominence or angle, known as the *angulus sterni* (*Ludovici*), which, although not usually visible, may always be felt. The angulus lies in the same plane as the body of the fifth thoracic vertebra.

The **xiphi-sternal junction** corresponds to the fibro-cartilage between the ninth and tenth thoracic vertebræ. Immediately inferior to the xiphi-sternal articulation is the **infra-sternal notch**, formed by the junction of the seventh costal cartilages with the sternum. Inferior to the notch is the **epigastric fossa** or **triangle**, bounded laterally by the seventh costal cartilages. The apex of the triangle forms an angle which varies considerably according to the shape of the chest, the average being about 70°. Not infrequently the eighth costal cartilage articulates with the sternum.

Fracture of the sternum is rare, and generally occurs at or close to the junction of the manubrium and the body; it may occur either from direct violence, or indirectly along with fracture of the vertebral column. Unlike that of the ribs, the periosteum covering the sternum is firmly adherent to the bone.

The **ribs**, which in well-nourished subjects cause no surface prominences, are readily visible in thin persons; in the obese they are very difficult to feel. In counting the ribs from the front, the *second* may always be identified by its relation to the angulus sterni. The *first rib* is to a large extent under cover of the clavicle. The inferior border of the pectoralis major and the first visible digitation of the serratus anterior afford reliable guides to the *fifth rib*. The infra-sternal notch is the guide to the medial end of the *seventh costal cartilage*. The second and third costal cartilages are almost horizontal; below this the cartilages ascend with increasing obliquity, that of the sixth being the first to present a distinct angle. The anterior end of the second intercostal space is the widest, while those of the fifth and sixth are very narrow.

The **costo-chondral junctions** may be indicated, on the surface, by a line drawn from the superior end of the para-sternal line to a point a finger's breadth posterior to the angle of the tenth costal cartilage.

The **internal mammary artery** crosses behind the medial ends of the superior five intercostal spaces, about half an inch from the edge of the sternum; as it descends it approaches a little nearer to the sternum. The vessel is accompanied by two veins which unite to form a single vein opposite the second interspace.

This artery is occasionally injured in punctured wounds of the chest. At the second or third intercostal space it is easily ligatured through a transverse incision, but at a lower level it is generally necessary to resect a portion of one of the costal cartilages.

THE LUNGS AND PLEURÆ.

The **apex** of the lung extends upwards into the root of the neck for a distance of one to two inches superior to the anterior extremity of the first rib, and is mapped out by a curved line drawn from the superior border of the sterno-clavicular

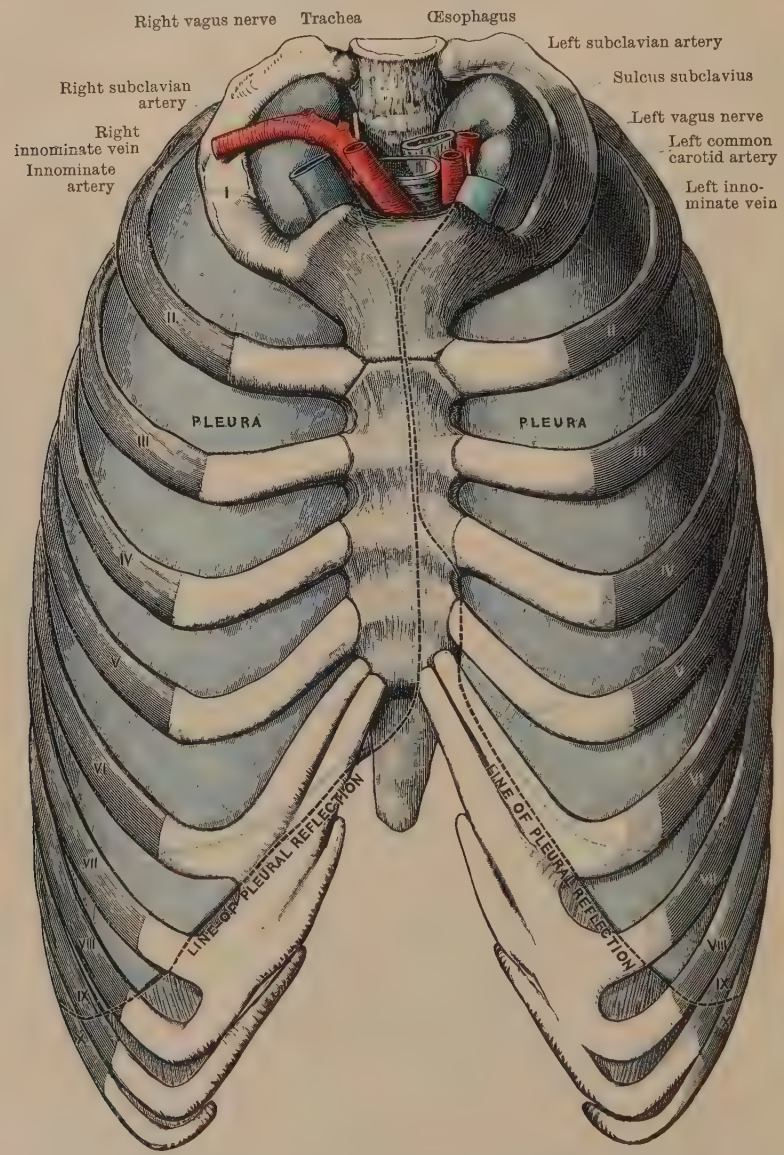

FIG. 1073.—DISSECTION OF A SUBJECT HARDENED BY FORMALIN INJECTION, to show the relations of the two pleural sacs as viewed from the front. The anterior and diaphragmatic lines of pleural reflexion are exhibited by black dotted lines, whilst the outlines of the lungs and their fissures are indicated by the blue lines. (From Cunningham.)

articulation across the sterno-mastoid to the junction of the medial and intermediate thirds of the clavicle, the highest part of the curve reaching from $\frac{1}{2}$ to $1\frac{1}{2}$ in. above the clavicle. The apex of the right lung reaches half an inch higher than that of the left lung. Intimately related to the apex of the cervical pleura are the **subclavian artery** and the **inferior cervical ganglion** of the sympathetic.

Both the **cervical pleura** and the **subclavian artery** may be injured by one of the fragments in a fracture of the clavicle; the scaleni muscles, however, affording considerable protection to the pleura. In ligaturing the third part of the subclavian artery, care must be taken not to injure the cervical pleura.

To delineate the **anterior border** of the **right lung**, draw a line from the superior border of the sterno-clavicular articulation to the centre of the manubrium sterni, and from there vertically downwards, in or slightly to the left of the median plane to the level of the sixth or seventh costal cartilage, or, it may be, even to the infra-sternal notch (Fig. 1073).

The **anterior border** of the **left lung** is mapped out by a corresponding line as far as the fourth costal cartilage; thence it is directed laterally along the inferior border of the fourth costal cartilage to the para-sternal line; it then passes downwards and slightly laterally across the fourth interspace, and curves medially behind the fifth costal cartilage and fifth interspace to reach the superior border of the sixth costal cartilage in the para-sternal line. The inferior part, therefore, of the anterior surface of the right ventricle is uncovered by lung and gives a completely dull note on percussion; this area is spoken of as the area of "*superficial or absolute cardiac dulness.*"

The level of the **inferior border** of the lung is practically the same on both sides; it is mapped out by a line extending laterally from the inferior extremity of the anterior border to the sixth costal cartilage in the mid-clavicular line, and thence in a slightly curved direction, with the convexity downwards, across the lateral aspect of the chest to the tenth thoracic spine. This line crosses the eighth rib in the mid-axillary line and the tenth rib in the scapular line (Figs. 1073 and 1074).

To indicate the position of the **oblique fissure** a line is drawn from the second thoracic spine across the interscapular region to the root of the spine of the scapula, and thence downwards and laterally across the infraspinous fossa, to end at the inferior border of the lung opposite the sixth costal cartilage, a little medial to the mammary line. When the arm is raised above the level of the shoulder, and the hand placed on the back of the head, the inferior angle of the scapula is rotated upwards and forwards so that the vertebral margin practically corresponds with the line of the oblique fissure.

FIG. 1074.—LATERAL VIEW OF THE RIGHT PLEURAL SAC IN A SUBJECT HARDENED BY FORMALIN INJECTION. The blue lines indicate the outline of the right lung, and also the position of its fissures. (From Cunningham.)

The **transverse fissure** of the right lung is mapped out by drawing a line from the anterior border of the lung, at the level of the fourth costal cartilage, laterally and slightly upwards to join the middle of the oblique fissure.

Pleuræ.—The **line of reflexion** of the **right pleura** from the back of the sternum may be said to correspond to the anterior border of the right lung.

On the **left side**, the pleural reflexion corresponds to the anterior border of the left lung as far as the inferior edge of the fourth chondro-sternal junction, from which point it diverges slightly and descends, behind the left border of the sternum, to the sixth costal cartilage (Fig. 1073). It is only occasionally that the anterior extremities of the fifth and sixth interspaces are uncovered by pleura.

The **right costo-diaphragmatic reflexion** (see Figs. 1074 and 1075) is indicated on the surface by a line drawn from the sixth or seventh chondro-sternal junction (sometimes the infrasternal notch) downwards and laterally to a point two inches vertically above the angle of the tenth costal cartilage; from that point the line is carried, with a slightly downward curve, across the lateral aspect of the chest to the twelfth rib at the lateral margin of the sacro-spinalis; thence it passes below the twelfth rib and reaches the vertebral column at the level of the superior border of the twelfth thoracic spine. The relation of the costo-diaphragmatic reflexion to the seventh, eighth, and ninth costal arches may be conveniently expressed by stating that it lies a little in front of the costo-chondral junction of the seventh, opposite that of the eighth, and a little behind that of the ninth. The **left costo-diaphragmatic reflexion** is indicated by a line drawn from a point opposite the sixth costal cartilage, a finger's breadth from its junction with the sternum, to a point one and a half inches vertically above the angle of the tenth costal cartilage, and thence to the vertebral column, as on the right side, but at a slightly inferior level.

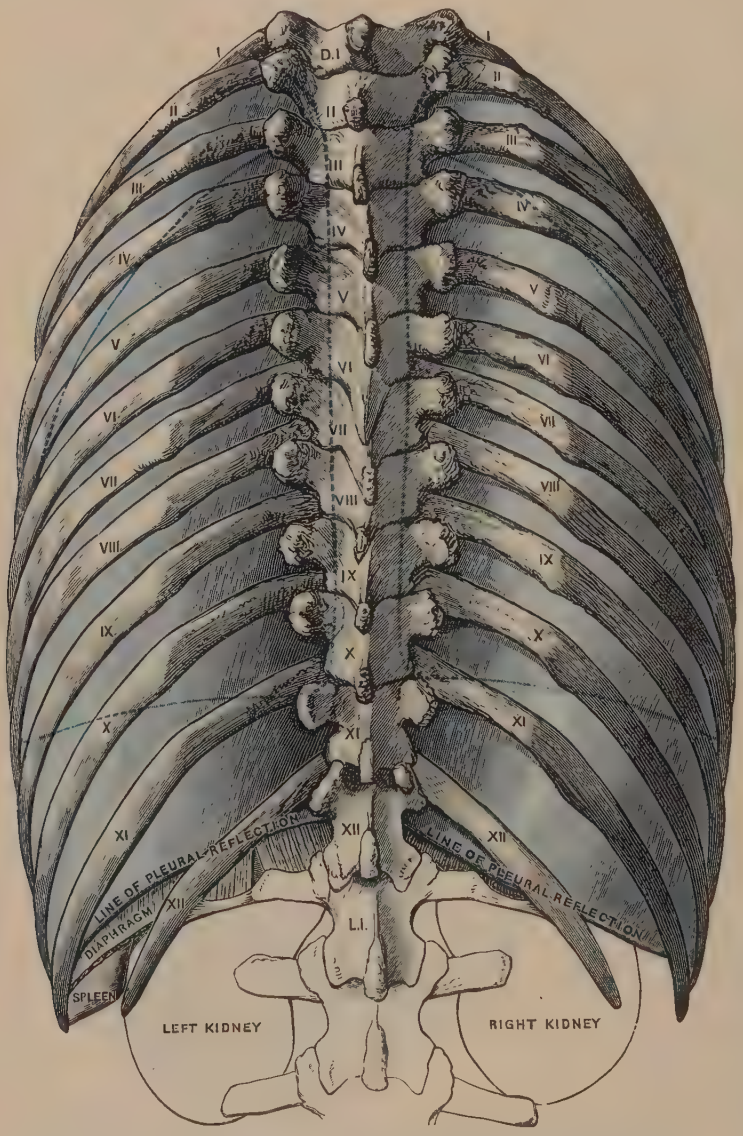

FIG. 1075.—DISSECTION OF THE PLEURAL SACS FROM BEHIND.

The blue lines indicate the outlines and the fissures of the lungs. (From Cunningham.)

The costo-diaphragmatic reflexion reaches its *lowest limit* a little behind the mid-axillary line two inches vertically above the tip of the eleventh costal cartilage,

a level which may be readily indicated, according to Cunningham, by a point in the mid-axillary line intersected by a horizontal line drawn round the trunk at the level of the lowest part of the extremity of the first lumbar spine (Fig. 1072). The same author localised the level of the diaphragmatic pleural reflexion in the mammary line at the point where this line is intersected by another horizontal line at the level of the spine of the last thoracic vertebra.

The **relations** of the **pleura** to the **twelfth rib** are of importance to the surgeon, especially in connexion with operations on the kidney (Figs. 1075 and 1076). When this rib is not abnormally short, the pleural reflexion crosses it opposite the lateral border of the sacro-spinalis muscle; hence an incision may be carried deeply as far as the apex of the angle formed by the twelfth rib and the lateral border of the sacro-spinalis without entering the pleura. When, however, the twelfth rib does not reach the lateral border of the sacro-spinalis, an incision carried upwards into the apex of the angle between

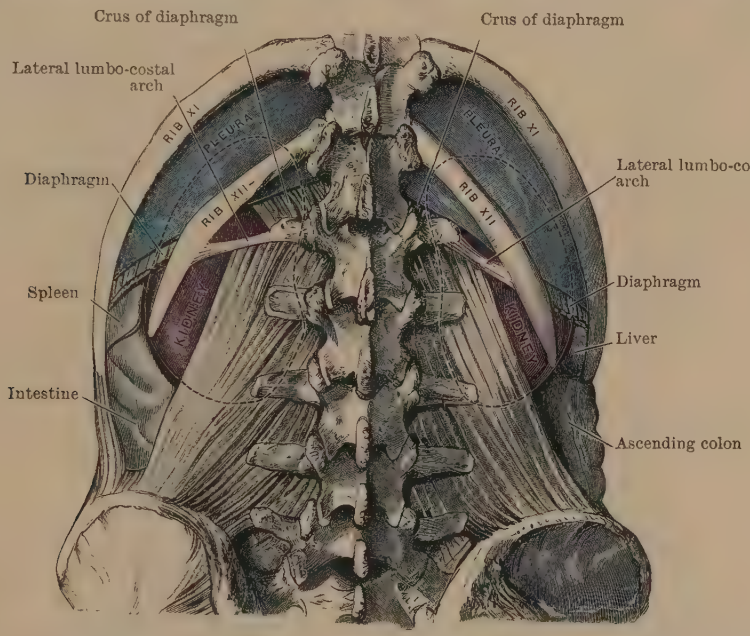

FIG. 1076.—DISSECTION FROM BEHIND TO SHOW THE RELATION OF THE TWO PLEURAL SACS TO THE KIDNEYS. Outlines of superior portions of the two kidneys are indicated by dotted lines. (From Cunningham.)

this muscle and the eleventh rib is certain to wound the pleura (Melsom). It is important, therefore, to count the ribs from above downwards, in order not to mistake the eleventh for the twelfth, when the latter is rudimentary.

Medial to the lateral edge of the sacro-spinalis the pleural reflexion lies below the level of the twelfth rib, and not infrequently descends as far as the transverse process of the first lumbar vertebra.

On the *right side* the **posterior mediastinal pleura**, as it passes from the posterior aspect of the pericardium, backwards, to the front of the vertebral column, sweeps over the right side of the œsophagus; hence malignant ulcers of the œsophagus are more likely to invade the right pleura than the left. On the *left side* the posterior mediastinal pleura passes from the lateral aspect of the bodies of the vertebræ on to the left side of the aorta. Hence, to evacuate pus from the posterior mediastinum, there is less risk of opening the pleura if the space is entered from the left side of the vertebral column.

The seat of election for *tapping the pleura* (*paracentesis pleuræ*) is the sixth or seventh costal interspace, a little in front of the posterior axillary fold. To allow of the introduction of a tube to drain away the pus from the pleural cavity in empyema, a portion of one of the ribs (sixth to ninth) is resected. The intercostal vessels and nerves, which lie in the groove at the inferior border of the rib, are avoided by removing the portion of bone subperiosteally. If the chest is opened in the scapular line, care must be taken not to resect either the seventh or the eighth ribs, which are exposed when the arm is elevated, but are overlapped by the inferior angle of the scapula when the arm is lowered.

Anteriorly, the **bifurcation** of the **trachea** lies opposite, or a little below, the *angulus sterni*, while posteriorly it lies a little below the level of the root of the spine of the scapula, opposite the fourth thoracic spine. The bifurcation takes place one vertebra higher in the infant than in the adult (Symington).

The septum between the right and the left bronchus lies a little to the left of the middle of the trachea, and the right bronchus is wider and more nearly in a line with the trachea than the left bronchus; hence the greater tendency of foreign bodies to enter the right bronchus.

The **roots** of the **lungs** are situated opposite the fourth, fifth, and sixth thoracic spines, midway between them and the vertebral margins of the scapulæ.

The lower end of the trachea, the bronchi, the vagi, and the left recurrent nerve, are all more or less surrounded by lymph glands, which, when enlarged, may exert injurious pressure upon them.

THE HEART AND GREAT VESSELS.

Viewed from the front, the **outline** of the **precordial area**, like that of the pericardial sac, is roughly triangular, the base of the triangle being below and the apex above. The boundaries are delineated upon the surface as follows:—

The *right side* of the triangle, formed by the right atrium, is indicated by drawing a lines lightly convex laterally from the superior end of the third to the sixth costal cartilage, a finger's breadth from the edge of the sternum; the curve attains its maximum opposite the fourth intercostal space, where it reaches one and a half inches from the median plane.

The *base* of the triangle, formed by the *margo acutus* of the right ventricle and to a very slight extent by the apical portion of the left ventricle, is almost horizontal, and corresponds to a line drawn from the inferior extremity of the right side of the triangle to the apex of the left ventricle, which lies behind the fifth left intercostal space, three and a half inches from the median plane, and half an inch medial to the mid-clavicular line. The base line crosses the xiphoid process at its junction with the body of the sternum.

The *left side* of the triangle, formed by the *margo obtusus* of the left ventricle, is indicated by a slightly curved line extending from the apex of the heart upwards to the inferior edge of the second interspace, a finger's breadth from the sternum, the convexity of the curve being directed laterally and slightly upwards.

The truncated *apex* of the triangle, which lies behind the sternum at the level of the second intercostal space, corresponds to the highest part of the heart, namely, where the auricles of the atria embrace the aorta and pulmonary artery.

The situation of the anterior part of the **coronary sulcus** is mapped out by a line drawn from the median plane, opposite the inferior border of the third left costal cartilage, downwards and laterally to the sixth right chondro-sternal junction; the line should be slightly convex upwards and to the right. The **right auricle** lies at, or a little to the right of, the median plane, at the level of the second intercostal space and the superior border of the third costal cartilage. The **left auricle** lies behind the second left intercostal space, close to the edge of the sternum.

The *diaphragmatic* or *inferior surface* of the heart rests upon the diaphragmatic or basal part of the pericardium. The *base*, or true *posterior surface*, of the heart is formed mainly by the **left atrium**, which is moulded posteriorly upon the œsophagus, the aorta, the bronchi, and the bronchial glands, the pericardium intervening. The left atrium extends behind the right atrium for a considerable distance to the right of the median plane.

In a radiographic examination in cases of general visceroptosis, the diaphragm, which should rise and fall opposite the xiphisternal junction, will be seen to be an inch or more lower down, while the heart is seen to hang more vertically than normal (cardioptosis).

In determining the position of the *cardiac orifices* and *their valves* it is to be remembered that they are all situated below and to the left of the anterior part of the coronary sulcus, and that they lie in the following order from above down-

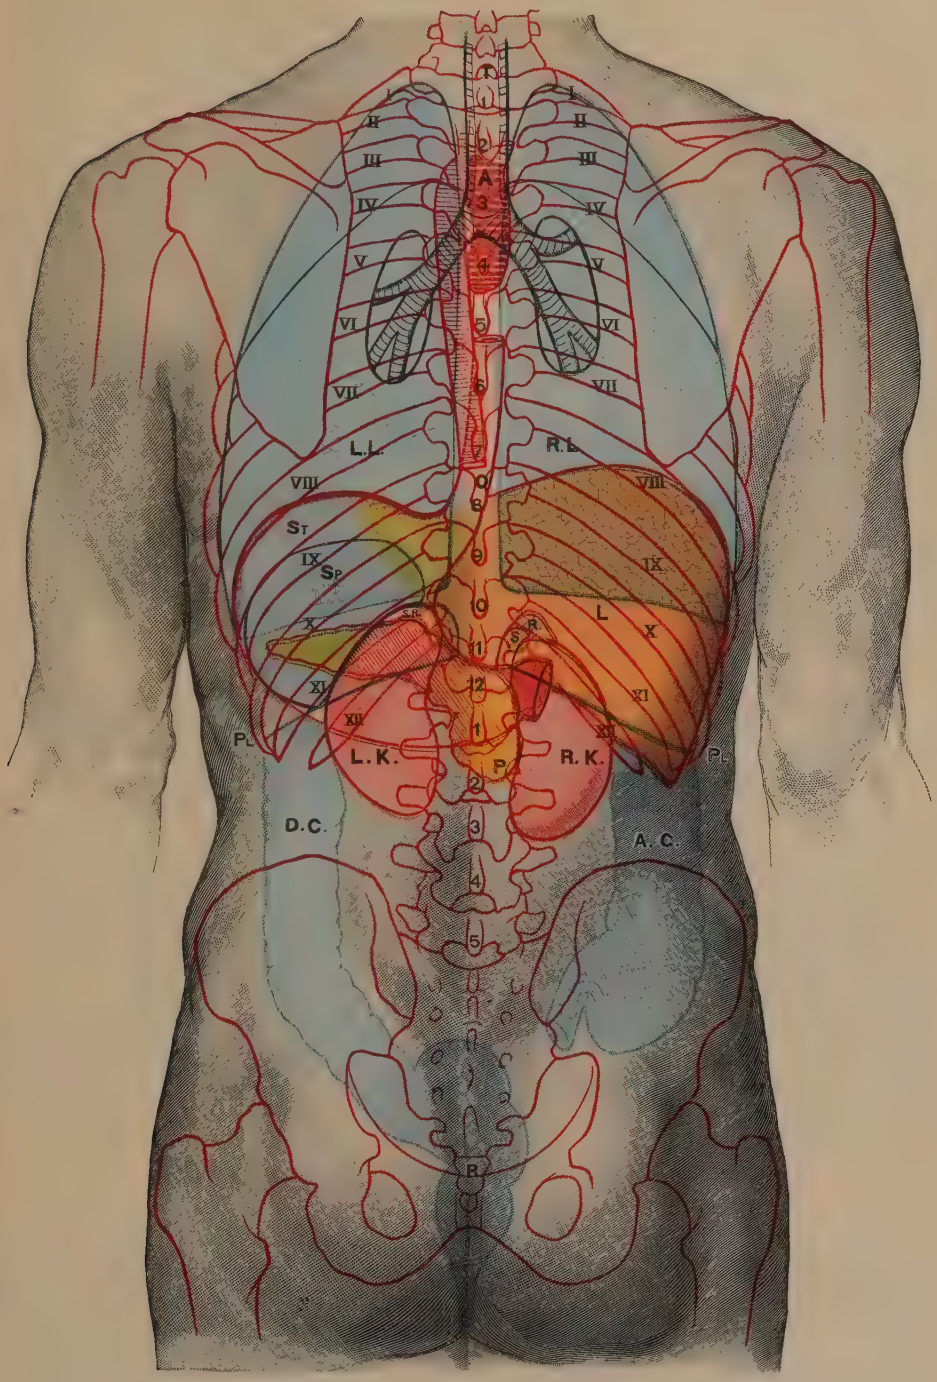

Fig. 1077.—Posterior Aspect of Trunk, showing Surface Topography of Viscera.

T.	Trachea.	Sp.	Spleen.	P.	Pancreas.

wards—viz., pulmonary, aortic, mitral, and tricuspid. When delineated on the surface they will be seen to lie within an ellipse whose long axis extends from the superior border of the third left to the sixth right chondro-sternal junction.

The **pulmonary orifice**, directed upwards and slightly backwards and to the left, lies opposite the superior border of the third left chondro-sternal junction; the **aortic orifice**, directed upwards, backwards, and to the right, lies further from the surface, behind the left half of the sternum, opposite the inferior border of the third costal cartilage; the **mitral orifice** lies at an inferior level, behind the left half of the sternum, opposite the fourth rib; the orifice of the opening is directed downwards, forwards, and to the left. The **tricuspid orifice**, situated nearer the anterior wall of the chest than the mitral, lies very obliquely behind the right half of the sternum at the level of the fourth and fifth cartilages and intervening space.

Although the first and second **sounds of the heart** are heard all over the cardiac area, the sounds produced by the individual valves are heard most distinctly, not directly over their anatomical situation, but over the area where the cavity in which the valve lies approaches nearest to the surface. Hence the mitral sound is best heard over the apex (mitral area), the tricuspid over the inferior part of the body of the sternum (tricuspid area), the aortic over the second right costal cartilage (aortic area), and the pulmonary over the second left intercostal space (pulmonary area).

In **tapping the pericardium** (paracentesis pericardii) the pleura will be avoided by making the puncture through the fifth or sixth left intercostal space as close as possible to the edge of the sternum. When, however, the pericardial sac is distended with fluid, the pleura is pushed laterally, and will therefore escape injury if the puncture is made at a safe distance lateral to the internal mammary vessels, viz., one inch lateral to the left border of the sternum.

To establish free drainage in suppurative pericarditis, the sixth left costal cartilage must be resected and the internal mammary vessels ligatured; the transversus thoracis and the pleural reflexion are then pushed aside and the pericardium exposed and incised.

The **ascending aorta** lies behind the sternum, opposite the second and third ribs, and, unless dilated, does not project beyond its right border. The superior border of the **aortic arch** lies at or a little above the centre of the manubrium sterni; in the child the vessel may reach as high as the superior border of the manubrium.

The **innominate** and **left common carotid arteries** diverge from either side of the median plane between the upper part of the manubrium sterni and the front of the trachea. A pin pushed directly backwards immediately above the middle of the supra-sternal notch will strike the medial border of the innominate artery a little below its bifurcation.

The **pulmonary artery** lies behind the left border of the sternum opposite the second interspace and the second costal cartilage.

The **left innominate vein** lies behind the superior part of the manubrium sterni, the **right** behind the medial end of the right clavicle. The **superior vena cava** lies immediately to the right of the margin of the sternum, opposite the first and second interspaces and the intervening second rib; its opening into the right atrium, behind the third chondro-sternal articulation, corresponds to the centre of the root of the right lung.

ŒSOPHAGUS.

The average length of the **œsophagus** in the adult is 10 in. (25 cm.); the distance from the incisor teeth to its commencement is 6 in.; to the point or level where it is crossed by the left bronchus, 9 in.; to the œsophageal opening of the diaphragm, 14 to 15 in.; to the cardiac orifice of the stomach, 16 in. These measurements, which are of great importance in diagnosing the seat of œsophageal obstructions, should be marked off from below upwards upon all œsophageal bougies and probangs. Posteriorly, the œsophagus extends from the level of the sixth cervical spine to that of the tenth thoracic, a little to the left of which is the situation at which the stethoscope is placed in order to hear the sound produced by the passage of fluid into the stomach.

Clinically it is important to bear in mind the relation of the œsophagus to the trachea and left bronchus, to the left recurrent nerve, to the bronchial and posterior mediastinal glands, to the descending thoracic aorta, and to the right posterior mediastinal pleura. Ulcers of the œsophagus are liable to open into either the trachea, the left bronchus, or the right pleura.

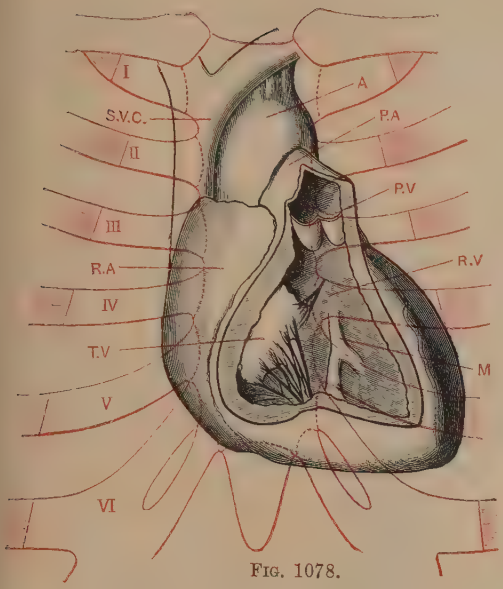

FIG. 1078.

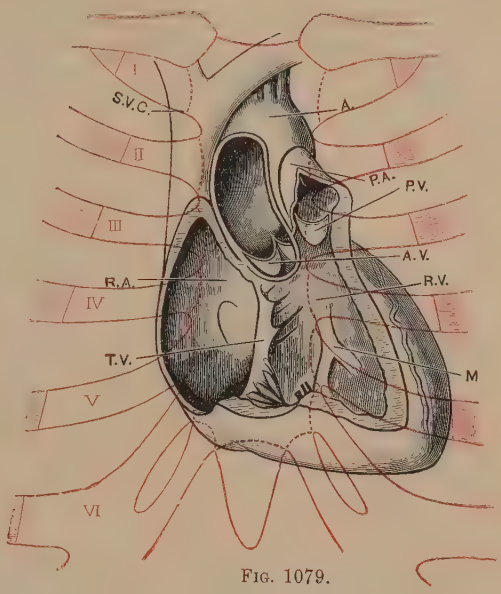

FIG. 1079.

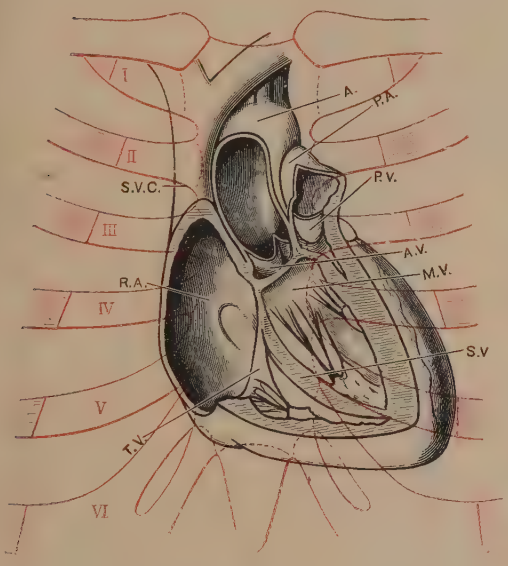

FIG. 1080.

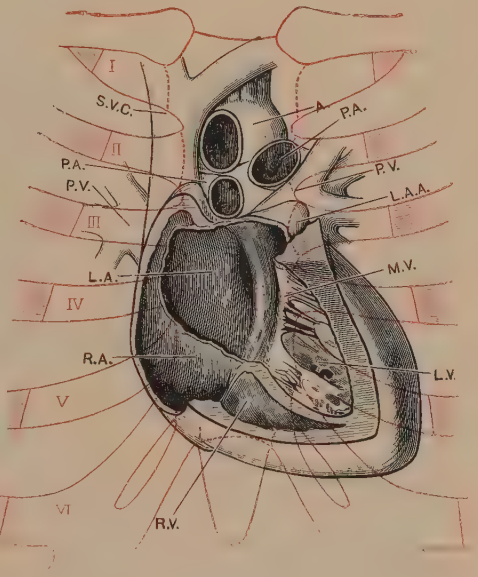

FIG. 1081.

From photographs of a formalin-hardened subject, with the heart dissected *in situ*, to show the relations of its cavities and valves to the anterior wall of the thorax.

In Fig. 1078 the anterior wall of the right ventricle has been removed and the pulmonary artery opened.

In Fig. 1079 the anterior walls of the ascending aorta and of the right atrium have been removed; also the anterior cusp of the tricuspid valve.

In Fig. 1080 the greater part of the interventricular septum has been removed, exposing the anterior cusp of mitral valve.

In Fig. 1081 the ascending aorta, anterior cusp of mitral valve, trunk of pulmonary artery, and interatrial septum have been removed; the cavities of the left atrium and left ventricle are exposed, also the left atrium and posterior cusp of mitral valve.

R.A.	Right atrium.	P.A.	Pulmonary artery.	M.V.	Mitral valve.
R.V.	Right ventricle.	P.V.	Pulmonary valve.	S.V.C.	Superior vena cava.
L.A.	Left atrium.	A.	Aortic arch.	P.V.	Pulmonary vein.
L.A.A.	Left auricle.	A.V.	Aortic valve.	M.	Moderator band.
S.V.	Interventricular septum.	T.V.	Tricuspid valve.		

The *veins* of the inferior end of the œsophagus open partly into the systemic veins and partly into the portal system; like those at the inferior end of the rectum they are liable to become varicose in conditions which give rise to chronic interference with the portal circulation.

The *lymph vessels* of the upper part of the œsophagus open into the inferior deep cervical glands, the remainder into the posterior mediastinal glands.

THE ABDOMEN.

THE ANTERIOR ABDOMINAL WALL.

The configuration of the abdomen varies with the age, sex, obesity, and muscular development of the individual. In the child it is wider above than below, while the reverse is the case in the adult female. It is most prominent in the region of the **umbilicus**, which is situated, normally, below the mid-point between the infra-sternal notch and the symphysis pubis, usually a little below the level of the highest part of the iliac crest, and opposite the middle of the body of the fourth lumbar vertebra. In the obese, and especially when the abdominal muscles have lost their tone, the umbilical region becomes prominent and more or less pendulous, so that the umbilicus may come to lie considerably below the normal level. In the child it is relatively lower than in the adult, in consequence of the undeveloped state of the pelvis.

In spare subjects the inferior end of the body of the sternum, the xiphoid process, and the costal margin, can readily be traced. The slight depression or notch formed by the seventh costal cartilages and the inferior border of the body of the sternum is termed the **infra-sternal notch**. Below the notch, and bounded on each side by the seventh, eighth, and ninth costal cartilages, is the **infra-costal angle**, which varies considerably according to the shape of the chest; it is relatively wider in the child than in the adult. The inferior border of the curve of the **tenth costal cartilage** is easily recognisable, and was selected by Cunningham as the level of the plane of separation (**infra-costal plane**) between the upper and middle abdominal zones.

The anterior abdominal wall is limited below by the fold of the groin and the crest of the pubes. In a spare muscular subject the recti, the furrows corresponding to the **inscriptiones tendineæ** (O.T. **lineæ transversæ**) and the supra-umbilical portion of the **linea alba**, can be readily made out. When the outline of the rectus is not visible the lateral border may be indicated by a line drawn from the tip of the ninth costal cartilage to the mid-point of a line joining the umbilicus and the anterior superior iliac spine, and from thence to the pubic tubercle. In the angle between the lateral border of the rectus and the ninth costal cartilage, on the right side, is a slight triangular depression which overlies the fundus of the **gall-bladder**. Between the inferior part of the lateral border of the rectus and the prominence above the anterior part of the iliac crest, caused by the lower muscular fibres of the external oblique, is another slight triangular depression, which corresponds to the inferior and narrow part of the aponeurosis of the external oblique muscle.

Close above, and almost parallel to, the medial half of the inguinal ligament is the **inguinal canal**, traversed by the **spermatic funiculus** (Fig. 1082); the latter can be felt to emerge at the subcutaneous inguinal ring immediately above the pubic tubercle. The **abdominal** and **subcutaneous inguinal rings** have been fully described elsewhere; the former is triangular in shape, with its apex directed superiorly and laterally, and its base immediately above the pubic crest. By invaginating the skin of the scrotum the little finger may be passed through the ring into the canal. It is to be noted that the neck of an *inguinal hernia* lies above the pubic tubercle, whereas the neck of a *femoral hernia* emerges below the medial end of the inguinal ligament, lateral to the pubic tubercle. The **abdominal inguinal ring**, an opening in the fascia transversalis, lies half an inch above a point a little medial to the middle of the inguinal ligament. The **inferior epigastric artery** may be mapped out by drawing a line from a point midway between the superior anterior iliac spine and the symphysis pubis towards the umbilicus. The vessel, together with the medial third of the inguinal ligament and the

inferior part of the lateral border of the rectus, bounds a triangle known as **Hesselbach's triangle.** As the inferior epigastric artery passes superiorly and medially to disappear behind the falx aponeurotica inguinalis and the lateral border of the rectus, it lies behind the spermatic funiculus immediately medial to, and below, the abdominal inguinal ring. The floor of Hesselbach's triangle is formed throughout by the fascia transversalis, superficial to which, over the medial half or so of the triangle, is the **falx aponeurotica inguinalis.** An **oblique inguinal hernia** leaves the abdomen at the abdominal inguinal ring and traverses the whole length of the inguinal canal; its coverings are therefore the same as those of the spermatic funiculus, and the neck of the sac lies lateral to the inferior epigastric artery, hence this variety of hernia is also termed *lateral inguinal hernia.* A **direct inguinal hernia**, on the other hand, instead of traversing the whole length of the inguinal canal, pushes before it that part of its posterior wall which is formed by the floor of Hesselbach's triangle. The neck of the sac, therefore, lies medial to the inferior epigastric artery, and this variety of hernia may be termed a *medial inguinal hernia.* If a direct hernia makes its way

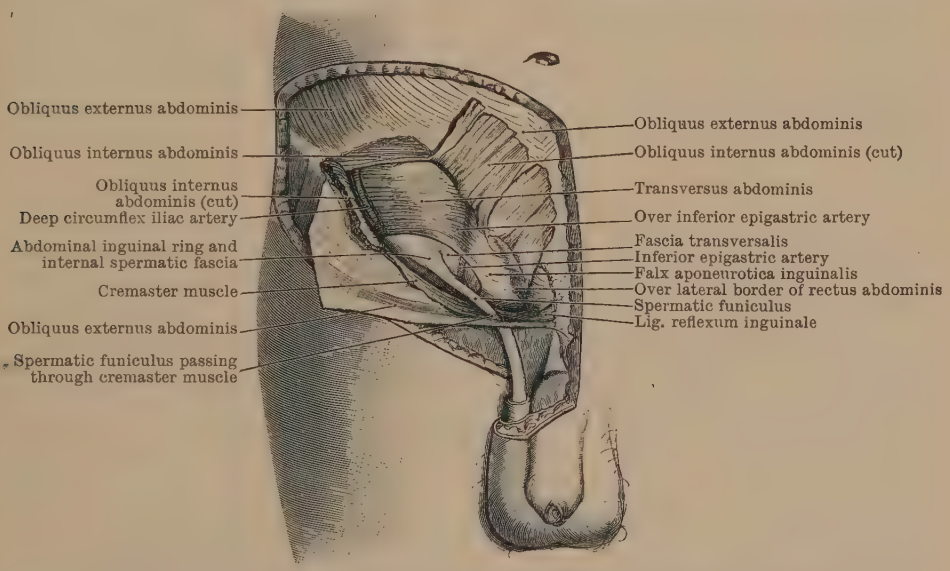

FIG. 1082.—THE GROIN. The structures seen on reflexion of part of the obliquus internus abdominis. (A. M. Paterson.)

through the medial part of Hesselbach's triangle, it derives a covering from the falx inguinalis, as well as from the fascia transversalis; if through the lateral part of the triangle, the lateral edge of the falx inguinalis curves round the medial side of the neck of the sac. To relieve the constriction at the neck of the sac, in the case of an *oblique inguinal hernia,* the edge of the knife is directed superiorly and laterally to avoid the inferior epigastric artery, while in a *direct hernia* the artery is avoided by dividing the constriction in a superior and medial direction. In an *oblique inguinal hernia* the sac lies within the internal spermatic fascia (fascia propria of the hernia), whereas in a *direct hernia* the fascia propria is derived from the fascia transversalis of Hesselbach's triangle. The extra-peritoneal fat which covers the outer surface of the hernial sac is sometimes hypertrophied to such an extent as to amount to a fatty tumour.

In a large proportion of children, at birth, the **vaginal process** of peritoneum, which connects the tunica vaginalis testis with the abdominal peritoneum, is still patent, especially on the right side. Should the bowel force its way along the patent process a **congenital inguinal hernia** arises. In the majority of the cases of congenital inguinal hernia it will be found that the tunica vaginalis testis has been shut off by closure of the lower part of the vaginal process, only the superior part remaining patent and forming the sac of the hernia.

In the child the persistence of a patent vaginal process can almost invariably be detected by rolling the cord between the finger and thumb; after the ductus deferens and spermatic vessels have slipped away from one's grasp the edge of the sac can be felt to follow them. In regard to the operation for the cure of inguinal hernia, it should be borne in mind that in the acquired form the *hernia produces the sac,* whereas in the congenital variety the *sac is the cause of the hernia*; it follows, therefore, that in the operation for *acquired* hernia the closure of the canal is as important as the removal or obliteration of the sac, while in a *congenital* hernia the most essential part of the operation is the closure of the neck of the sac, and as the muscular and fascial apparatus forming the walls of the canal are often well developed (especially in children), they should be interfered with as little as possible. A patent vaginal process may persist during adult life without any bowel descending into it; on the other hand, years after birth, bowel may suddenly enter it. In practically all oblique inguinal herniæ, which develop suddenly in children as well as in adolescents and young adults, the *sac* is of congenital origin.

In the ordinary form of hydrocele the fluid is confined to the tunica vaginalis testis, but when the vaginal portion of the processus vaginalis remains patent, the hydrocele may extend upwards into the inguinal canal, and may or may not communicate with the general peritoneal cavity. In the condition known as encysted hydrocele of the cord the patent funicular process is shut off both from the tunica vaginalis testis and from the peritoneal cavity.

Abdominal Incisions.

Before proceeding to deal with the abdominal cavity reference must be made to some anatomical points connected with the more typical incisions made by surgeons in opening the abdomen.

Incisions in the Median Plane.—Median line incisions through the linea alba have the advantage of being comparatively bloodless and rapid of execution, of dividing no motor nerves, and of enabling the surgeon to expose a wide area of the abdomen. Unless special precautions are taken, however, they are more liable to be followed by a ventral hernia.

Above the umbilicus the linea alba is comparatively broad, so that the edges of the recti are separated by a distinct interval, which may be of considerable width in obese subjects and multiparous women. Deep to the linea alba is the transversalis fascia, which is so thin and adherent that the two structures form practically a single layer. The extraperitoneal fat, which forms a comparatively thick stratum, must not be mistaken for omentum. The peritoneum presents itself as a thin, bluish, semi-transparent membrane. If it is necessary to prolong the incision downwards below the level of the umbilicus, it should skirt its left margin so as to avoid the round ligament of the liver. If, in closing a median supra-umbilical laparotomy wound, the surgeon merely sutures the edges of the stretched linea alba without opening into the rectal sheaths, a hernia may result. To ensure against it the medial borders of the recti are exposed by opening into their sheaths along each edge of the wound. In closing the wound, the deepest suture (continuous) includes on each side the posterior layer of the rectal sheath along with the split linea alba, the transversalis fascia, and the peritoneum. This gives a substantial "first line of defence." The next suture takes up some of the fibres of the medial edges of the recti, along with the anterior layer of their sheaths. The skin is sutured separately. By the above procedure the edges of the recti are brought into actual contact and a double-layered linea alba is fashioned, one layer behind the margins of the recti and the other in front of them.

Below the umbilicus the medial edges of the recti are practically in contact, so that an incision between them opens into the rectal sheath on both sides.

The nearer the opening into the abdomen approaches the symphysis pubis, the more likely is the bladder to be encountered; this applies more especially in children in whom the bladder extends higher up out of the pelvis. Before opening the abdomen, therefore, by a low median incision, the bladder should be emptied; in supra-pubic cystotomy, on the other hand, it is intentionally filled so as to elevate the peritoneum (superior false ligament of the bladder) well above the symphysis. Below this peritoneal layer is the **space of Retzius,** occupied by a pad of extra-peritoneal fat which must be separated by blunt dissection before the bladder wall is actually exposed. In opening the bladder the pre-vesical veins, which ramify on its surface, are avoided as far as possible. Above the pubes the fascia transversalis recedes somewhat from the posterior surface of the recti, leaving behind it a cellular interval which must not be mistaken for the space of Retzius.

If a transverse incision is added to the inferior end of a supra-umbilical median incision, free access may be obtained to the hypochondriac as well as to the epigastric region. Before dividing the fibres of the rectus, however, the anterior layer of the sheath is stitched to them to prevent

their retraction. In dividing the posterior layer of its sheath the terminal portions of the ninth and tenth intercostal nerves need not be injured as they run in a transverse direction.

Incisions through the Recti.—In opening the abdomen by **longitudinal incisions through the recti**, the superior epigastric artery will be encountered above the umbilicus, and the inferior epigastric below it. The nearer the opening approaches the lateral border of the rectus, the more will its nerve-supply be injured. **Above the level of the umbilicus**, the posterior layer of the rectal sheath is well developed; and in closing the wound it is included in the same suture as the transversalis fascia and the peritoneum, the three together forming a most efficient "first line of defence." The higher up and further lateral the incision is made through the rectus, the more will the posterior layer of the sheath be found to be made up of transverse muscular fibres prolonged inwards from the transversus abdominis muscle. **Below the level of the umbilicus**, the posterior layer of the rectal sheath is much thinner, and where it ceases, namely, about midway between the umbilicus and the pubes, it constitutes what is known as the linea semicircularis **(semilunar fold of Douglas)**. Below this level, therefore, the "deep closure" of a laparotomy wound through the rectus is less secure than is the case at a higher level. It is all the more important, therefore, to see that the edges of the anterior layer of the sheath are accurately sutured.

Incisions lateral to the Rectus.—Longitudinal incisions lateral and parallel to the lateral border of the rectus are as far as possible to be avoided, firstly, because they divide the motor nerves, and, secondly, because the abdominal wall is almost entirely aponeurotic, and, therefore, a hernia is liable to result.

Incisions lateral to the rectus, **above the level of the umbilicus**, are generally made more or less parallel to the costal margin. Such incisions give access to the gall-bladder and bile-ducts. The fibres of the external oblique muscles are divided transversely, but those of the internal oblique and transversus muscles may be divided more or less parallel to the fibres. The abdominal portions of the eighth, ninth, and tenth thoracic nerves lie between the two deep muscles, running in a medial and slightly downward direction, so that it is practically impossible to avoid dividing one or other of them.

In the iliac regions, to reach the cæcum and vermiform process on the right side, and the pelvic colon on the left side (colostomy), it is customary, by using what is known as the "gridiron incision," to split the three abdominal muscles in the direction of their fibres. The external oblique is split in the direction of the skin incision, which is made obliquely from above downwards and medially. After retracting the edges of this muscle the fibres of the internal oblique and transversalis muscles are split horizontally. The abdomen is then opened by dividing the transversalis fascia and peritoneum. If a comparatively large opening is required the branch of the deep circumflex iliac artery, which ascends between the internal oblique and transversus muscles, a little medial to the anterior superior iliac spine, is divided and ligatured, while the ilio-hypogastric and ilio-inguinal nerves are to be avoided. If it is necessary to extend the incision in a medial direction, the lateral part of the anterior layer of the sheath of the rectus is opened and the rectus muscle retracted medially; while the inferior epigastric artery, now exposed, is pushed aside or ligatured before the opening in the fascia transversalis and peritoneum is enlarged.

Distribution of Sensory Nerves in Anterior Abdominal Wall.

A knowledge of the segmental distribution of the sensory fibres of the anterior rami of the lower intercostal nerves enables us to appreciate the significance of the so-called girdle pain often associated with lesions of the spinal medulla and its nerve-roots. In tuberculous disease of the vertebral column, for example, the girdle pain may be an early symptom of the disease, and when present it affords a valuable guide to the situation of the disease in the vertebral column. The seventh thoracic nerve supplies the skin at the level of the epigastric triangle, the eighth and ninth, that between it and the umbilicus, the tenth that at the level of the umbilicus, the eleventh and twelfth that between the umbilicus and groin.

THE ABDOMINAL CAVITY.

Subdivisions of the Abdominal Cavity.—To simplify the topography of the abdominal viscera the abdomen is arbitrarily divided into nine regions by two horizontal and two vertical planes. Of the two horizontal planes, the **superior** or **infracostal plane** is at the level of the lowest part of the tenth costal cartilages; the **inferior** or **intertubercular plane** is at the level of the tubercles of the iliac crests. The **two vertical planes** correspond upon the surface to a line drawn vertically upwards on each side from a point midway between the anterior superior iliac spine and the pubic symphysis. Superiorly, these vertical planes generally strike the tip of the ninth costal cartilages. The subdivisions of the **superior zone** are termed the *epigastric* and *right* and *left hypochondriac regions*, of the **middle zone**

the *umbilical* and *right* and *left lumbar regions*, of the **inferior zone** the *hypogastric* and *right* and *left iliac regions*. The epigastric, umbilical, and hypogastric regions may be further divided into right and left halves by the median plane. The **xiphisternal junction** is on a level with the fibro-cartilage between the ninth and tenth thoracic vertebræ. The **infracostal plane** passes through the superior part of the third lumbar vertebra; the **intertubercular plane** through the fifth lumbar vertebra, about one inch above the sacral promontory. The umbilicus is situated usually from one to two inches above the intertubercular line.

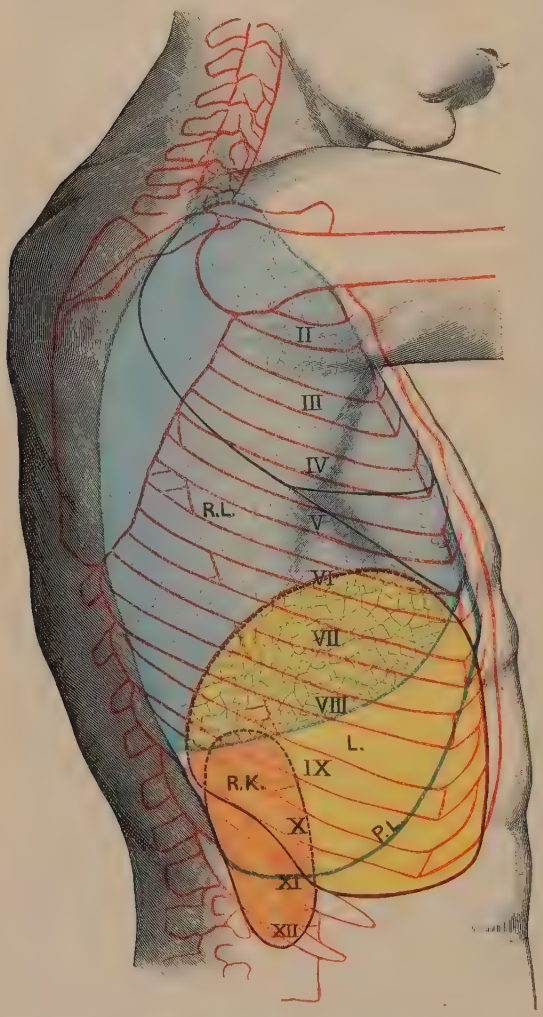

Fig. 1083.—Lateral Aspect of Trunk, showing Surface Topography of Viscera.

R.L. Right lung. R.K. Right kidney.
L. Liver. P.L. Pleura.

In the method of surface topography employed by Addison the plane of separation between the superior and middle abdominal zones is placed midway between the superior border of the manubrium sterni and the superior border of the pubic symphysis. It will be found to lie at or near the mid-point between the xiphisternal junction and the umbilicus. Posteriorly, this plane strikes the inferior border of the first lumbar vertebra, and it passes so constantly through the pylorus that it may with advantage be termed the **transpyloric plane.**

The **peritoneal cavity** may be regarded as a large and complicated lymph sac which is intimately related to the abdominal viscera, and more especially to the gastro-intestinal canal. Inflammatory infections of the peritoneum are therefore almost always secondary to lesions of the viscera. The peritoneal lymph sac is brought into direct communication with the subperitoneal lymph vessels of the diaphragm through stomata which open upon the peritoneum covering the abdominal surface of that muscle. With the object, therefore, of diminishing septic absorption after operations for peritonitis, the patient is kept in the half-sitting posture, and pelvic drainage is established. The healthy peritoneum, in virtue of the vital action of its endothelial cells, is endowed with great absorptive properties, and, when irritated, has the power of throwing out an abundant exudation, the cell-elements of which are actively phagocytic.

The reflexion of the peritoneum and its relations to the various organs have been fully described in the section on the Digestive System.

The attachment of the **transverse mesocolon** to the posterior abdominal wall is at the level of the first lumbar vertebra, and lies, therefore, a little above the infracostal plane. The attachment, which ascends slightly as it passes from right to left, crosses the right kidney, the descending part of the duodenum, and the head of the pancreas, after which its attachment follows the anterior border of the pancreas. The *peritoneal subdivision above this attachment* is roofed in by the

diaphragm, and includes the superior part of the great sac, and, behind it, the larger portion of the omental bursa. The organs related to this area of the peritoneum are the liver, along with the bile-ducts and gall-bladder, the stomach and part of the duodenum, the spleen, the pancreas, the upper parts of the kidneys, and the suprarenal glands. Suppuration connected with any of these organs is liable to spread upwards under the cupola of the diaphragm, producing what is known as *subphrenic abscess.*

The attachment of the **mesentery** of the **small intestine** extends from the left side of the second lumbar vertebra downwards to the right iliac fossa. The attachment may be mapped out on the surface by drawing a line from a point on the transpyloric line, one inch to the left of the median plane, to the mid-point of a line drawn horizontally between the right anterior superior iliac spine and the median plane.

Subdivisions of the Peritoneal Cavity.—From the surgical point of view the peritoneal cavity may be arbitrarily divided into **four great subdivisions**: namely, a supracolic, a right infracolic, a left infracolic, and a pelvic. All these subdivisions communicate freely with one another behind the anterior abdominal wall, as well as on each side, along the gutter-like channels in the loins. It is along these gutters that pus readily makes its way from the upper part of the abdomen along the lumbar regions into the iliac regions, and thence into the pelvis; and, on the other hand, the pus may ascend from the pelvis along the same channels, especially when the patient is in the recumbent posture.

The highest (subphrenic) region of the **supracolic compartment** is further subdivided into a right and left portion by the falciform ligament.

The **omental bursa** may be looked upon as a diverticulum of the first-mentioned subdivision.

The subphrenic lymph plexus communicates, by means of lymph vessels which pierce the diaphragm, with the subpleural plexus on its superior surface; hence pus confined under tension in either of these spaces is liable to give rise to secondary infection of the corresponding pleural cavity. By adhesions of the transverse colon and greater omentum to the anterior abdominal wall, the supracolic subdivision of the peritoneal cavity may become more or less completely shut off from the rest of the abdomen. Suppuration in the right half of the phrenicocolic subdivision is generally secondary to leakage from an ulcer of the first part of the duodenum or to disease of the gall-bladder and bile-ducts; while the left half of the space is more usually infected from the stomach. The best method of draining the supracolic subdivision of the peritoneal cavity is to pass a tube through the **hepato-renal pouch** (Morrison). The entrance to this pouch lies lateral to the gall-bladder between the inferior margin of the liver above and the right flexure of the colon below. The bottom of the pouch is formed by the reflexion of the peritoneum from the superior part of the kidney on to the fascia transversalis covering the aponeurosis of origin of the transversus abdominis muscle below the tip of the twelfth rib. To drain it, a tube is introduced into it either from the wound in the anterior abdominal wall, or, still better, through a puncture opening made through the loin lateral to the kidney, in the angle between the twelfth rib and the lateral border of the sacro-spinalis muscle. Another drainage route is by a tube passed from the wound in the anterior abdominal wall into the omental bursa, through either the gastro-hepatic ligament or the great omentum.

The **right infra-colic subdivision** lies above and to the right of the mesentery of the small intestine. It is bounded, above, by the right and middle two-thirds of the transverse colon and the corresponding part of its mesentery, while laterally it is limited by the cæcum and ascending colon. At its right inferior angle are the ileo-cæcal junction and the vermiform process; at its right upper angle is the right flexure of the colon, while at its left upper angle is the inferior part of the duodenum, crossed by the superior mesenteric vessels. In rare instances this portion of the duodenum is so compressed between these vessels and the vertebral column that partial, or even complete, obstruction results. The condition has been named gastro-mesenteric ileus, but a more correct term would be duodeno-mesenteric ileus.

The organs related to this subdivision are, in addition to the parts of the large intestine already mentioned, coils of small intestine, the inferior third of the right kidney, the right ureter, the inferior half of the descending and the horizontal part of the inferior portions of the duodenum.

Suppuration in connexion with the organs in this area involves more especially the right lumbar region, and may extend upwards along the colon into the subdiaphragmatic region, or downwards into the pelvis minor. To drain this region a tube is introduced into the right lumbar region either through the anterior abdominal wall or through a stab-wound in the loin lateral to the ascending colon.

The **left infra-colic subdivision**, which lies below and to the left of the mesentery, narrows as it passes upwards and reaches to a higher level than the right infra-colic subdivision. Inferiorly, it is directly continuous at the superior aperture of the pelvis with the peritoneal cavity of the pelvis minor. Above, it is bounded by the left third of the transverse colon and its mesentery, and, still more posteriorly, by the inferior surface of the body of the pancreas; laterally it is bounded by the descending and iliac portions of the colon. At its right upper angle is the duodeno-jejunal flexure, lying immediately to the left of the vertebral column, in the angle between it and the inferior surface of the pancreas. At its left superior angle is the left flexure of the colon, while at its left inferior angle is the junction of iliac with pelvic colon. This subdivision of the peritoneal cavity, in addition to containing the majority of the coils of the small intestine, is related to the inferior third of the left kidney, the left ureter, the lower part of the abdominal aorta and vena cava, and the inferior mesenteric and common iliac vessels. Drainage of this subdivision may be established through the left loin, or by a tube introduced down to the bottom of the pelvis, namely, into the recto-vesical pouch in the male, and into or through the recto-vaginal pouch (pouch of Douglas) in the female.

On account of the oblique manner in which the mesentery proper is attached to the posterior abdominal wall, it follows that in order to examine the organs related to the right infra-colic subdivision of the abdomen, the coils of small intestine should be displaced downwards and to the left, while to investigate the left infra-colic subdivision they should be carried upwards and to the right.

ABDOMINAL VISCERA.

Liver.—The *anterior margin of the liver*, as it crosses the costal angle, can readily be determined by palpation and light percussion; it passes from the eighth left to the tip of the tenth right costal cartilage, and crosses the median plane at the level of the transpyloric line. In the *mid-clavicular line* it reaches down to a point a little below the most inferior part of the tenth right costal cartilage. Above the left costal margin the anterior margin passes upwards and to the left to join the left border of the liver at the fifth interspace in the mammary line. The *highest part of the liver*, which corresponds also to the highest part of the right arch of the diaphragm, reaches, during expiration, to the level of the fourth intercostal space in the mammary line. To the right of the median plane the superior surface of the liver is too far removed from the anterior wall of the chest, and overlapped by too thick a layer of lung substance, to be accurately determined by percussion. *Behind the sternum* the superior surface reaches to the level of the sixth chondro-sternal junctions. To the left of the median plane the superior limit of the liver cannot be determined by percussion since it merges into the cardiac dulness. The base or **right lateral surface** extends from the level of the seventh to the level of the eleventh rib in the mid-axillary line and is separated by the diaphragm from the lower part of the right lung and pleura.

The **falciform ligament** of the liver lies, as a rule, a little to the right of the median plane.

By dividing the *round ligament*, which passes backwards and upwards within its free margin, the liver can be rotated backwards around its transverse axis so as to expose more of its inferior surface; this procedure is sometimes taken advantage of by the surgeon in cases in which there is unusual difficulty in reaching the cystic duct or the ductus choledochus. The ligament is sutured before the abdominal wall is closed.

The **anterior surface** of the liver may be reached through a median incision, extending downwards from the xiphoid process, or by an oblique incision, a finger's-breadth below and parallel to the right costal margin. To obtain free access to the **superior surface** the eighth and ninth costal cartilages must be resected; the seventh cartilage should, if possible, be avoided; otherwise the pleural cavity may be opened into. Division of the round and falciform ligaments allows of greater downward displacement of the liver. To reach the upper part of the **lateral surface** of the right lobe, portions of the seventh and eighth ribs should be resected in the mid-axillary line, and both the pleural and peritoneal cavities must be traversed.

Gall-Bladder.—The relation of the fundus of the **gall-bladder** to the surface of the body is subject to considerable variation. Normally it is situated behind the angle between the ninth costal cartilage and the lateral border of the right rectus; exceptionally, it is pendulous and suspended from the liver by a more or less distinct mesentery; or it may be elongated and drawn downwards by adhesion to the duodenum or colon. When displaced downwards it is liable to be mistaken for a movable kidney, but may be distinguished from that by the fact that although it may be pushed backwards into the lumbar region it returns at once to its habitual position, immediately behind the anterior abdominal wall, as soon as it ceases to be manipulated.

The **cystic duct** is enclosed in the right extremity of the superior border of the gastro-hepatic ligament. It is about an inch and a half in length, is sharply bent upon itself close to its origin at the neck of the gall-bladder. It joins the hepatic duct at a very acute angle. The passage of a probe along the *normal* duct is rendered difficult by the marked flexure at its commencement, as well as by the folded condition of its mucous membrane; hence also the frequency with which calculi become impacted at the neck of the gall-bladder.

In excising the gall-bladder, it is an advantage to divide and ligature the cystic artery and duct before proceeding to detach the organ from the inferior surface of the liver, and care must be taken not to injure the common duct or the portal vein.

The **bile-duct**, about three and a half inches in length, lies, in its *superior third*, close to the right free border of the gastro-hepatic ligament. When cutting into this, the most accessible part of the duct, it should be drawn forwards by the finger introduced behind it, through the epiploic foramen; the portal vein, which must be avoided, lies posterior and a little to the left of the duct. The *middle third* of the duct lies a little to the right of the commencement of the gastro-duodenal artery behind the superior part of the duodenum about a finger's-breadth from the pyloro-duodenal junction. The *inferior third* of the duct, which passes downwards and to the right, is intimately related to the pancreas; in about two out of three instances it is so embedded in the posterior aspect of its head that it cannot be freed by blunt dissection. Close to its termination the duct is joined by the main pancreatic duct of Wirsung, the two opening separately, but close together, at the bottom of a diverticulum, which pierces the wall of the duodenum obliquely, and opens at the summit of a small papilla situated at the inferior part of the medial wall of the descending part of the duodenum, about four inches from the pylorus. When a calculus becomes impacted in the ampulla there is retention of the pancreatic as well as of the biliary secretion. Frequently, however, the gland possesses an accessory pancreatic duct (duct of Santorini) which opens into the duodenum at a higher level than the main duct, with which it also communicates.

A calculus in the ampulla may be reached either by opening the duodenum from the front (trans-duodenal route), or by freeing the duodenum and gaining access to the duodenum from behind (retro-duodenal route). In the latter instance an incision is made, lateral to the right border of the descending part of the duodenum, through that portion of the peritoneum which passes upwards and to the right from the superior layer of the transverse mesocolon, over the superior part of the pars descendens of the duodenum on to the anterior surface of the right kidney. By blunt dissection, directed medially, behind the duodenum, that organ, along with the adjacent part of the head of the pancreas, can be separated from the kidney and vena cava, and folded over towards the left like a door on its hinges. In freeing the bile-duct from the posterior aspect of the head of the pancreas a vein of considerable size will be encountered; this vein, which returns the blood from the pancreatico-duodenal system of arteries, lies close to the

bile-duct as it ascends behind the head of the pancreas to open into the commencement of the vena portæ. Of the lymph glands related to the bile passages it is to be remembered that one lies at the neck of the gall-bladder, another at the junction of the cystic and hepatic ducts, while a third lies close to the termination of the bile-duct. When these glands are enlarged and indurated, care must be taken not to mistake them for impacted gall-stones. On account of the very free anastomosis between the lymphatics of the gall-bladder, bile-ducts, and pancreas, infective inflammatory processes readily spread from one organ to the other.

Stomach.—The stomach lies almost entirely within the left half of the epigastric region and in the left hypochondriac region. The **cardiac orifice**, which lies 1 in. below and to the left of the œsophageal opening in the diaphragm, is about 4 in. from the surface, and corresponds, on the anterior surface of the body, to a point over the seventh left costal cartilage 1 in. from the median plane. The **pylorus**, which is generally partly overlapped by the anterior margin of the liver, lies in, or a little to the right of the median plane; when the stomach is *empty* it generally lies in the median plane, when *distended* it may reach two, or even three inches to the right of the median plane. Passing from the superior to the inferior border of the pylorus opposite its junction with the duodenum is the **anterior pyloric vein** (Mayo). This vein affords a useful visible guide to the position of the pylorus. Another guide is furnished by the ring-like thickening of the pyloric sphincter which projects into the commencement of the duodenum (like the cervix uteri into the vagina), and can be readily palpated through its thin wall. The pyloric portion of the stomach is practically bisected by a horizontal plane which passes through the abdomen at the level of a point midway between the jugular notch of the sternum and pubic symphysis (Addison); it lies, therefore, three to four inches below the infra-sternal notch, midway between it and the umbilicus, opposite the first lumbar vertebra. The highest part of the **fundus of the stomach** corresponds to the left vault of the diaphragm, and lies at the level of the fifth rib in the mammary line, a little above and behind the apex of the heart. The **greater curvature** crosses behind the left costal margin opposite the tip of the ninth costal cartilage, that is to say, where the transpyloric line intersects the left lateral line. The lowest part of the great curvature, situated generally in the median plane, extends down to, or a little above, the infra-costal plane, about two inches above the umbilicus. The **lesser curvature** and the adjacent part of the anterior wall of the stomach are overlapped by the anterior margin of the liver.

Radiography of Stomach.—Radiograms of the stomach, taken after an "opaque meal," show that the form and position of the stomach in the living subject differ considerably from that which it presents in the cadaver.

In the cadaver, owing to loss of muscular tone, it presents itself as a more or less empty pear-shaped bag with collapsed and flaccid walls. The same applies to a large extent to the stomach as seen in the operating room, its normal tonicity being almost entirely held in abeyance by the anæsthetic.

In the living subject, the form and position of the stomach are found to vary not only according to the amount of food it contains, but also according to whether the patient occupies the erect or the recumbent posture. The most reliable, as well as the most useful, information regarding the form, the position, and the motor activity of the stomach is obtained by "screen" examinations and radiograms taken with the patient in the erect posture. When examined in this way, after partly filling the stomach with an "opaque meal," the organ is seen to possess a distinctly J-shaped form. The stem of the J, which is represented by the **body of the stomach**, lies immediately and entirely to the left of the vertebral column. The **fundus**, which is slightly more expanded than the body, reaches up to the left cupola of the diaphragm; it is represented in the skiagram as a light semilunar shadow, the horizontal inferior margin of which corresponds to the superior limit of the meal. This clear semilunar area is due to the rising up of the gaseous contents of the stomach to the highest part of the cavity. The **cardiac orifice** is seen to lie opposite the left side of the fibro-cartilage between the tenth and eleventh thoracic vertebræ. The shadow of the curved **pyloric portion of the stomach**, after crossing the left side of the vertebral column opposite the third and fourth lumbar vertebræ, ascends as the **pyloric canal** to join the duodenum at or a little to the right of the

median plane, opposite the second (not infrequently the third) lumbar vertebra. The **pylorus** itself is represented by a light disc due to a hiatus in the continuity of the bismuth, caused by contraction of the pyloric sphincter. The lowest portion of the **greater curvature**, which generally lies at or a little to the left of the median plane, reaches, in the erect posture, down to the level of the middle or inferior border of the fourth lumbar vertebra, or, in other words, to the umbilicus and the highest part of the iliac crest.

As more food enters the stomach its capacity is increased by lateral expansion rather than by any elevation of its fundus or downward expansion of its greater curvature. The normal tonic action of the gastric muscle is able to hold up the meal against the action of gravity to the level of the cardiac orifice.

When, as not infrequently happens, the normal muscular tonicity of the stomach is lost, the bismuth meal is no longer held up against the action of gravity, but at once sinks to the most dependent part of the stomach, where it lies as in a flaccid sac, and gives rise to a crescentic shadow which may reach down almost, or even quite, to the level of the pubes.

In gastroptosis, and in general visceroptosis, the whole stomach may be displaced downwards without any great loss of its tonicity.

During a "screen" examination after an opaque meal, the peristaltic movements of the stomach can be seen to pass in distinct wave-like indentations from left to right along the greater curvature, and to increase in force as they approach the pylorus.

When the stomach is hypertrophied and dilated, as a result of pyloric obstruction, the peristaltic waves are more pronounced, and the bismuth shadow extends well over to the right of the median plane, owing to the dilated pyloric antrum and pyloric canal being carried over to the right, in front of the superior part of the duodenum. The stomach tends, therefore, to lose its somewhat J-shaped tubular form, and the axis of its body becomes more oblique. In the infant and young child the stomach is flask-shaped rather than fish-hook or J-shaped, and its axis is less vertical than in the adult. The elongated form of the adult stomach is acquired as a result of the erect posture. Occasionally the axis of the adult stomach inclines more towards the horizontal and gives rise to a röntgenogram shaped more like the horn of a steer (steer-horn stomach).

It must be remembered that the only really fixed part of the stomach is the region of the cardia, so that the form and position of the organ may be considerably influenced by the condition of the neighbouring organs. For example, it may be displaced downwards and to the left by enlargement of the liver, upwards by distension of the intestines, and to the right by distension of the left colic flexure.

Overlying the stomach is an important surface area known to clinicians as the **semilunar space of Traube.** This space, which yields a deeply tympanitic note on percussion, is bounded, above, by the inferior margin of the left lung; below, by the left costal margin; to the right, by the anterior margin of the left lobe of the liver; behind and to the left, by the anterior border and anterior basal angle of the spleen. The line of the costo-diaphragmatic pleural reflexion crosses the space about midway between its superior and inferior limits. The tympanitic area of the space is diminished superiorly by pleuritic effusion, towards the right by enlargement of the liver, and towards the left by enlargement of the spleen.

Perforation of an ulcer on the *anterior wall* of the stomach leads to extravasation into the greater sac of the peritoneum, while if the perforated ulcer is on the *posterior wall*, extravasation takes place into the omental bursa. The close relation of the splenic artery and its branches to the posterior wall of the stomach explains the severe hæmorrhage which is sometimes caused by a posterior gastric ulcer. The surgeon may reach the posterior wall of the stomach through the gastro-colic ligament, or, after throwing upwards the greater omentum and transverse colon, by traversing the transverse mesocolon; by the former route the posterior wall of the stomach is reached through the anterior wall of the omental bursa, in the latter through its posterior wall.

When a **partial resection of the stomach**, for malignant disease, is performed, the bleeding is controlled by ligaturing the main vessels at an early stage of the operation. These are the

right and left gastrics at the lesser curvature, the gastro-duodenal behind the first part of the duodenum, and the right and left gastro-epiploics at the greater curvature. The left gastric should be ligatured as near the cardia as possible, so that the whole chain of lymph glands along the lesser curvature may be removed. Care is taken to remove also all the glands which lie behind the first part of the duodenum in relation to the gastro-duodenal artery and head of the pancreas, as well as those along the right half of the greater curvature in relation to the right gastro-epiploic artery. If the disease has spread to the retro-peritoneal lymph glands, surrounding the cœliac artery, above the pancreas, the chances of a permanent recovery are very remote.

In the classical "no-loop" **gastro-enterostomy operation** a longitudinal opening in the commencement of the jejunum is anastomosed by suturing it to an opening in the posterior wall of the stomach, near the greater curvature. The jejunum is applied to the stomach in such a way that it maintains its normal direction, namely, obliquely upwards and to the left. To bring the surfaces of the two organs in contact, surgeons are in the habit of protruding the posterior wall of the stomach through an opening made in the transverse mesocolon, on the proximal side of the arch formed by the middle and left colic arteries. A better plan, however, is to make an opening also into the omental bursa through the gastro-colic ligament a little below the gastro-epiploic vessels, and then to bring the jejunum into contact with the posterior wall of the stomach by pushing it (the jejunum) upwards through the opening in the transverse mesocolon. By this plan the posterior wall of the stomach along with the jejunum can be protruded through an opening in the gastro-colic ligament; they can then easily be delivered out of the abdominal cavity, and another advantage is that the transverse colon can be replaced into the abdominal cavity while the anastomosis is being made.

When the posterior wall of the stomach and transverse colon are held down by adhesions, a long loop of jejunum is brought up in front of the greater omentum and transverse colon and anastomosed to the anterior wall of the stomach.

The Duodenum.—The duodenum is the widest, thickest, and most fixed part of the small intestine. For descriptive purposes it is divided by anatomists into three parts. From the surgical standpoint it may with advantage be subdivided into a supra-colic and an infra-colic portion, the former, comprising the superior and the upper half of the descending part, being situated above the attachment of the transverse mesocolon; while the latter, comprising the lower half of the descending part along with both subdivisions of the third part, is situated below this attachment. To expose the supra-colic portion the greater omentum and the transverse colon must be pulled downwards, while to expose the infra-colic portion they are thrown upwards along with the transverse mesocolon.

The first portion proper **(pars superior)** lies in the right part of the epigastric region, medial to the gall-bladder, where it is overlapped by the quadrate lobe of the liver. As regards its **blood-supply**, it occupies the frontier zone between the cœliac and superior mesenteric vascular areas, and the vessels which supply it vary considerably in their size and mode of origin.

This peculiarity of its blood-supply may partly account for the relative frequency with which this portion of the intestine is found to be the seat of ulceration. The first inch or so of the duodenum possesses some degree of mobility, being surrounded by the same two layers of peritoneum which invest the stomach. Beyond this it is in direct contact posteriorly and inferiorly with the pancreas, while descending behind it are the common bile-duct and the gastro-duodenal artery. The relations must be borne in mind in performing the operation of pylorectomy. When an ulcer of the superior part perforates, extravasation takes place, in the first instance, into the supra-colic compartment of the peritoneum, thence into its hepato-renal pouch, and subsequently down along the ascending colon into the right iliac fossa,—hence the possibility of mistaking the condition for an acute appendicitis. Perforation of the ulcer into the peritoneal cavity is often prevented by the duodenum becoming adherent especially to the pancreas, to the gall-bladder, or to the omentum.

If the finger is passed upwards, backwards, and to the left, immediately above the first part of the duodenum and behind the right free border of the lesser omentum, it will pass through the foramen epiploicum into the omental bursa of the peritoneum.

The second portion of the duodenum **(pars descendens)** descends in the epigastric and umbilical regions a little medial to the right lateral plane. The attachment of the transverse mesocolon crosses it about its middle, while posteriorly it lies in front of the hilum and medial border of the right kidney, from which it is separated

by loose areolar tissue. The procedure necessary to mobilise this portion of the duodenum has been referred to already.

The *horizontal portion* of the **inferior part** of the duodenum occupies the superior part of the umbilical region, and crosses the median plane about one inch above a line joining the highest part of the iliac crests; behind its commencement is the superior part of the right ureter.

The *ascending portion* of the **inferior part** of the duodenum crosses the infra-costal plane, and ascends upon the left side of the vertebral column opposite the second and third lumbar vertebra.

The röntgen shadow of the first portion of the duodenum usually takes the form of a more or less vertical truncated cone ("duodenal cap" or "bulb") with its base directed towards the pyloric ring. Owing to the fact that the opaque meal is held up for a short time in the bulb, the shadow is denser than that caused by the other divisions of the duodenum which are rapidly traversed by the meal. And as the first part of the duodenum contains no valvulæ conniventes the outline of the bulb is smooth and nearly symmetrical. In duodenal ulcer the outline of the bulb is generally distorted, due partly to the ulcer itself and partly to the spasm which it sets up.

The **duodeno-jejunal flexure**, which lies in the transpyloric plane one inch to the left of the median plane, is the landmark which the surgeon makes for when he wishes to identify the commencement of the jejunum (Fig. 925, p. 1195). To find the flexure the greater omentum and transverse colon should be thrown upwards and the finger passed along the inferior layer of the transverse mesocolon to the left side of the vertebral column. The flexure lies in the angle or recess formed by the left side of the second lumbar vertebra and the inferior surface of the body of the pancreas. With the finger in this recess the commencement of the jejunum may be hooked forward a little to the left of the superior mesenteric vessels at the root of the mesentery. In connexion with the duodeno-jejunal junction is the **inferior duodenal fossa**, formed by a fold of peritoneum which stretches from the left side of the fourth or ascending part of the duodenum upwards to become attached to the peritoneum of the posterior abdominal wall close to the medial border of the left kidney. The free edge of the fold and the mouth of the fossa look upwards. This is one of the situations at which an internal hernia sometimes develops, the sac, as it enlarges, extending further and further into the extra-peritoneal tissue on the posterior abdominal wall. Should strangulation occur, the inferior edge of the orifice must be divided in a downward direction, in order to avoid the inferior mesenteric vein which curves round the anterior and superior aspects of the orifice (Treves).

Jejunum and Ileum.—To expose the coils of the jejunum and ileum completely, the greater omentum, along with the transverse colon and the greater curvature of the stomach, must be turned upwards. On account of the oblique attachment of the mesentery, the greater number of the coils lie in the left infra-colic peritoneal compartment, where they extend upwards to the left of the vertebral column as far as the attachment of the transverse mesocolon and the inferior surface of the pancreas; here they lie in front of the inferior pole of the left kidney, in the angle of the left colic flexure.

The only certain means which the surgeon has of distinguishing the superior from the inferior coils of small intestine is by their relation to the duodeno-jejunal flexure and the ileo-cæcal junction. Occasionally the plicæ circulares and the aggregated lymph nodules can be seen from the peritoneal aspect and the jejunum and ileum thereby respectively identified. The *terminal portion of the ileum*, which is attached by the inferior end of the mesentery to the superior part of the right wall of the pelvis major, crosses the superior aperture of the pelvis minor, and ascends along the medial edge of the cæcum before opening into it. The terminal loop of the ileum may be hooked up by passing the finger along the medial side of the cæcum downwards over the medial border of the psoas major and the external iliac vessels into the pelvis minor.

To bring out a loop of the upper jejunum in the operation of jejunostomy the abdomen is opened through the left rectus muscle at, or a little above, the level of the umbilicus. The

duodeno-jejunal flexure is then identified and a catheter is introduced into the jejunum, and the bowel itself is then sutured to the edges of the opening in the divided peritoneum.

Meckel's diverticulum, which is due to persistent patency of the proximal portion of the vitelline duct, is situated usually from two to three feet above the valve of the colon; its average length is two inches. Springing from the anti-mesenteric border of the ileum, its termination is usually free, but it may be adherent either to the anterior abdominal wall, to the mesentery, or, more rarely, to one of the adjacent viscera. When its termination is fixed it may give rise to strangulation of the intestine.

Cæcum.—The cæcum occupies the right iliac region and extends from the anterior superior spine of the ilium to the superior aperture of the pelvis minor. **When empty**, it is generally more or less completely overlapped by small intestine, and frequently also by the greater omentum. **When partly distended**, the cæcum comes in contact with the anterior abdominal wall immediately above the lateral half of the inguinal ligament. **In the normal condition** it is completely surrounded by peritoneum, and can, therefore, along with the vermiform process, be readily delivered out of the abdomen. In chronic constipation, associated with intestinal

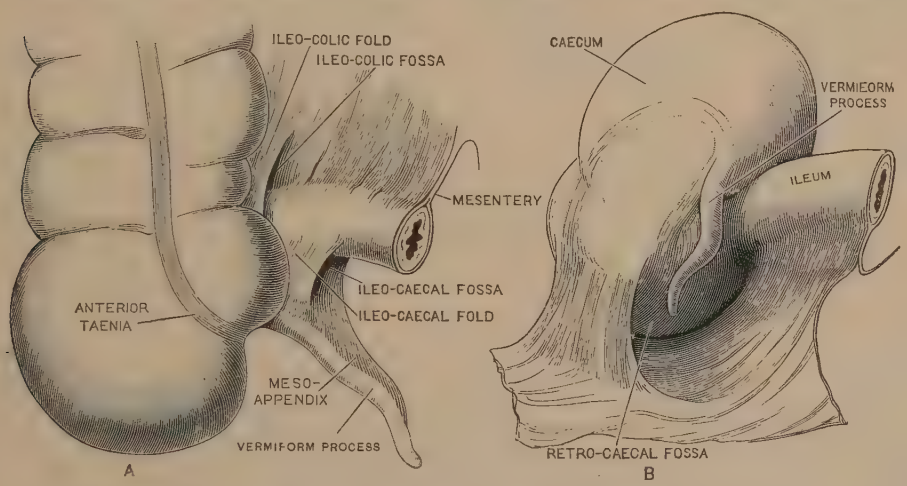

FIG. 1085.—THE CÆCAL FOLDS AND FOSSÆ.

In A, the cæcum is viewed from the front; the mesentery of the vermiform process is distinct, and is attached above to the inferior surface of the portion of the mesentery going to the end of the ileum. In B, the cæcum is turned upwards to show a retro-cæcal fossa, which lies behind it, and the beginning of the ascending colon. (From Birmingham.)

atony, the cæcum is thin-walled, dilated, abnormally movable, and often prolapses into the pelvis.

The position of the ileo-cæcal valve corresponds, on the surface of the body, to the medial angle between the intertubercular and right lateral lines, while the orifice of the vermiform process is one inch lower. It is to be noted that the lower end of the ileum protrudes somewhat into the cæcum, and that its circular muscular fibres are prolonged into the flaps of the colic valve. Both of these anatomical arrangements favour the occurrence of intussusception. In infants, other predisposing causes are: (1) the relatively rapid enlargement of the lumen of the large intestine as compared with the small; (2) the greater mobility of the cæcum; and (3) the frequent presence of a mesentery to the ascending colon.

Vermiform Process.—The vermiform process (O.T. vermiform appendix), which springs from the postero-medial aspect of the cæcum, one inch below the ileo-cæcal junction, is provided with a well-developed "meso-enteriole" derived from the posterior aspect of the lowest part of the mesentery of the ileum. It is this portion of the posterior layer of the mesentery which sometimes develops a band-like thickening, which, by dragging upon the inferior end of the ileum, produces the kink to which attention has been directed by Arbuthnot Lane. The artery of the vermiform process is the only vessel which supplies the process; it occupies the

free border of the meso-enteriole and gives off several branches which pass between its two layers to reach the organ. In amputating the vermiform process the artery is ligatured on the proximal side of its first branch in order to control the blood-supply to the stump of the process. The fact that the vermiform process is supplied by a single artery predisposes it to gangrene should the vessel become thrombosed, or should the circulation in it be interfered with by kinking as a result of adhesions.

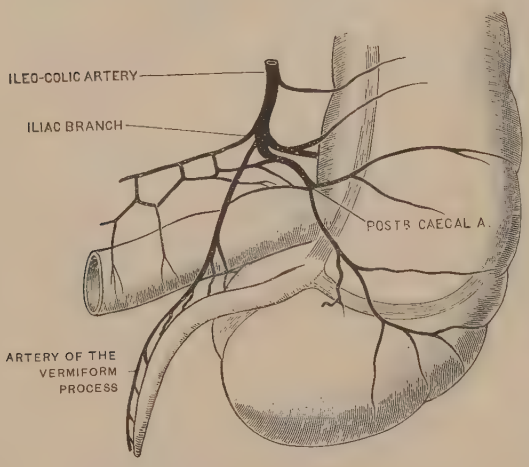

FIG. 1086.—THE BLOOD-SUPPLY OF THE CÆCUM AND VERMIFORM PROCESS.

The illustration gives a view of the cæcum from behind. The artery of the vermiform process, and the three tæniæ coli springing from the base of the process, should be specially noted. (Modified by Birmingham from Jonnesco.)

The vermiform process will generally be found to pass either upwards and medially, behind the lower end of the ileum, or downwards and medially, so as to overhang the external iliac vessels at the superior aperture of the pelvis minor; less frequently it ascends in the pouch behind the cæcum and commencement of the ascending colon. When, as not infrequently happens, the retro-cæcal fossa is prolonged upwards to form a pouch behind the colon, the vermiform process almost invariably ascends into it, and should it be diseased, it may give rise to a retro-cæcal abscess. The abscess may perforate the posterior wall of the cæcum, or it may ulcerate through the posterior peritoneum; in the latter case the suppuration may spread upwards, in the loose fatty sub-peritoneal tissue behind the colon, into the lumbar and perinephric regions; and it may reach even the under surface of the diaphragm and form a subphrenic abscess. When, in the course of its development, the cæcum has failed to complete its descent, the vermiform process may lie in the lumbar region in relation to the inferior pole of the kidney. When it dips downwards into the pelvis minor it may become adherent to the pelvic colon, the rectum, or the bladder, and in the female to the uterine tube or the ovary.

To find the vermiform process, the best plan is simply to pull the cæcum out of the wound, and if the parts are normal the process will be delivered along with it; if, on the other hand, the cæcum and vermiform process are tacked down by adhesions, the vermiform process is best discovered by following the anterior tænia coli to the root of the process.

Ascending Colon.—The ascending colon, after crossing the iliac crest, lies deeply in the right lumbar region upon the fascia covering the quadratus lumborum and the adjacent aponeurotic origin of the transversus abdominis. Between the bowel and the fascia is a quantity of loose cellular tissue and fat, which may be the seat of a large abscess, secondary, (1) more especially, to disease of the colon itself, (2) to disease of a retro-colic vermiform process, or (3) to disease of the right kidney. This cellular tissue is directly continuous above with a thin layer lining the inferior surface of the diaphragm; hence the suppurative process may extend upwards, giving rise to one form of subphrenic abscess. In some cases the ascending colon is completely surrounded by peritoneum, and it may even be provided with a distinct mesentery. The latter condition is almost invariably present in infants suffering from extensive ileo-cæcal intussusception. After the invagination has been reduced the mesentery proper is seen to be continuous, through the ascending mesocolon, with the mesentery of the transverse colon.

In order to resect the cæcum and ascending colon the surgeon mobilises it by dividing the peritoneum along its line of reflexion from the lateral aspect of the colon on to the abdominal wall. The colon, along with the posterior peritoneum medial to it, is then stripped, from the lateral side towards the median plane, off the quadratus lumborum, the psoas, and the inferior pole of the right kidney. While this is being done, the branches of the ileo-colic and right

colic vessels which pass laterally to supply the gut are secured, and the lymph vessels and associated lymph glands are removed along with the bowel. As the peritoneum is stripped off, care must be taken not to injure the important structures which lie behind it, namely, the duodenum, the ureter, and the testicular or ovarian vessels.

The **right colic flexure** reaches upwards beneath the tenth costal cartilage into the most inferior part of the right hypochondrium, where it lies immediately to the right of the gall-bladder, between the liver and the inferior half of the anterior surface of the kidney. Posteriorly, it is separated from the anterior surface of the right kidney by a quantity of loose cellular tissue; hence by dividing the peritoneum to the right side of the flexure it can readily be mobilised and separated from the kidney.

Transverse Colon.—The transverse colon crosses the lower part of the umbilical region immediately below the greater curvature of the stomach. In cases of chronic constipation it may form a U-shaped or V-shaped loop, extending down to the level of the pubes. When this is the case the natural kinking at the right and left colic flexures becomes more acute, and tends, therefore, to aggravate the constipation. In such cases the right and left portions of the transverse colon often lie parallel and close to the ascending and descending colon, respectively, like the barrels of a gun.

The transverse colon receives its blood-supply from the arch formed by the middle and left colic arteries. The arch lies in the posterior wall of the bursa omentalis between the two layers of the transverse mesocolon.

In resecting portions of the stomach for malignant disease, the surgeon removes also the glands which lie between the two layers of the gastro-colic ligament in relation to the right gastro-epiploic vessels. At this step of the operation care must be taken not to endanger the blood-supply of the transverse colon by injuring the middle colic artery.

The **left colic flexure** is more acute and more fixed than the right flexure; and it is situated at a higher level as well as more deeply. A tumour originating in this portion of intestine lies generally under cover of the left costal margin, and is therefore difficult to palpate.

To expose the left colic flexure, the omentum along with the transverse colon and the body of the stomach is turned upwards. To mobilise it for the purpose of resection the surgeon must divide (1) the phrenico-colic ligament, which attaches it to the diaphragm opposite the eleventh rib; (2) the left border of the greater omentum, which attaches it to the stomach; and (3) the left portion of the transverse mesocolon, which attaches it to the left extremity of the pancreas.

Descending Colon.—The descending colon, like the ascending, is deeply placed in the lumbar region and is related to the inferior half of the lateral border of the left kidney. It is less frequently provided with a mesentery than is the ascending colon.

Iliac Colon.—The iliac colon commences at the junction of the posterior and middle thirds of the iliac crest, and ends at the superior aperture of the pelvis minor by joining the pelvic colon. It possesses no mesentery and is connected to the fascia covering the iliacus and psoas major muscles by loose areolar tissue. Towards its termination it turns medially immediately above and parallel to the inguinal ligament, and at its junction with the pelvic colon it lies in front of the external iliac artery. Although, as a rule, it is entirely overlapped by coils of small intestine, it can frequently be felt by firm palpation at the lateral part of the left iliac fossa, because its muscular wall is comparatively thick and generally contracted.

Pelvic Colon.—The pelvic colon, in consequence of possessing a well-developed mesentery, forms a freely movable loop which, though usually confined to the pelvis minor, may, when distended, rise well up into the abdomen. It is this section of the large intestine which is opened for the purpose of making an artificial anus in malignant disease of the rectum.

The pelvic colon varies considerably in length, the average being sixteen or seventeen inches. It is relatively longer and of greater calibre in the child than in the adult. It is the part of the large intestine especially involved in the condition known as **megalocolon** or Hirschsprung's disease—a congenital abnormality in which the large intestine is greatly dilated and hypertrophied.

When the pelvic colon is thrown upwards and to the right so as to spread out

its mesentery, the latter is seen to be attached in an inverted V-shaped manner to the posterior wall of the pelvis. At the apex of the V is a small peritoneal pouch, the **inter-sigmoid fossa**, situated just in front of the ureter as it crosses the termination of the common iliac artery to enter the pelvis minor. This fossa is one of the situations at which an internal retro-peritoneal hernia may originate. The mouth of the fossa looks downwards and to the left, while above and to its right is the sigmoid artery. The fossa affords a guide to the commencement of the pelvic portion of the left ureter. On account of the V-shaped attachment of this mesentery it is convenient to speak of the pelvic colon as possessing an ascending or proximal and a descending or distal limb. At the junction of the proximal limb with the termination of the iliac colon is a more or less well-marked flexure (the "last kink" of Arbuthnot Lane). It is to the proximal limb of the pelvic colon that the divided inferior end of the ileum is anastomosed in the short-circuiting operation of **ileo-sigmoidostomy.**

In the author's operation of transplanting the ureters into the large intestine for incontinence of urine, the result of epispadias in the female, and of ectopia vesicæ in either sex, the left ureter is implanted into the ascending limb of the pelvic colon and the right ureter into its descending limb.

By dividing the attachment of the mesentery of the pelvic colon in the operation of excision of the rectum, the pelvic colon may be mobilised sufficiently to allow of its being brought down and sutured to the skin in the sacral region or even to the anal region. Further, the mobility of the pelvic colon is such that after resection of the descending and iliac colon and mobilisation of the left colic flexure, the divided ends of the bowel can be sutured together without undue traction.

After operations on the female genital organs by the abdominal route—for example, after abdominal hysterectomy—the surgeon makes use of the pelvic colon and its mesentery by spreading them out over the pelvis so as to roof it in, and so prevent any of the coils of small intestine from becoming adherent in the pelvis.

Kidneys.—The kidneys lie behind the peritoneum, and extend higher up than is often supposed, and laterally they do not extend so far away from the vertebral column as is almost invariably depicted; hence it is that, unless enlarged, the kidneys can seldom be felt through the abdominal wall. The right kidney as a rule lies a little lower than the left, as well as a little further away from the median plane. The hilum of the right kidney lies 2 in. from the median plane; that of the left $1\frac{1}{2}$ in. from the median plane. For practical purposes the **hilum** of the kidney may be regarded as opposite a point on the anterior abdominal wall a finger's-breadth medial to the tip of the ninth costal cartilage; and a line joining the two hila crosses the vertebral column opposite the fibro-cartilage between the first and second lumbar vertebræ, that is to say, a little below the transpyloric line. The *highest point* of the kidney is situated two inches from the median plane, on a level with a line crossing the abdomen midway between the xiphisternal and transpyloric planes. The *lowest point* of the kidney reaches down to, or a little below, the infra-costal plane.

The student should make himself familiar with the feel of the parts in relation to the kidneys, as far as they can be made out by introducing the hand through a median abdominal incision.

The superior half of the anterior surface of the **right kidney** is felt, at the bottom of the hepato-renal peritoneal pouch, by passing the hand deeply into the right hypochondrium, between the anterior margin of the liver and the right flexure of the colon. The inferior half is palpated by passing the hand deeply into the highest part of the right infra-colic peritoneal compartment; its free peritoneal surface lies in the angle of the right flexure of the colon. The second portion of the duodenum overlaps both the supra- and infra-colic portions of the medial border of the right kidney. When the right kidney is excised by the abdominal route, the peritoneum is divided lateral to the ascending colon and right colic flexure, and these structures, along with the descending part of the duodenum, are stripped off the organ in a medial direction, until the hilum and the renal vessels are reached.

The **left kidney** is crossed transversely, about its middle, by the body of the

pancreas and the splenic vessels. To palpate the supra-pancreatic portion, the hand is passed through the left portion of the gastro-colic ligament, upwards behind the stomach, into the superior part of the omental bursa. The spleen will be felt to overlap the lateral border of the kidney. To palpate the infra-pancreatic portion of the organ, which is covered by the peritoneum continued downwards from the attachment of the inferior layer of the transverse mesocolon, the hand is passed deeply into the upper part of the left infra-colic peritoneal compartment as far as the angle of the left flexure of the colon. This area of the kidney is overlapped by coils of small intestine, while passing transversely laterally in front of it are the left colic artery and its branches. When the left kidney is excised by the transperitoneal route, the left colic flexure and the descending colon are mobilised by dividing the peritoneum lateral to them so as not to injure the left colic artery.

In addition to their true fibrous capsules, the kidneys are surrounded by and enveloped in a well-marked fatty capsule. Outside this perinephric fat is a more or less well-defined fibrous envelope, known as the **renal fascia** or fascia of Gerota, which forms, as it were, a sheath to the organ. Hence, just as in the case of the prostate and thyreoid glands, the kidney possesses, in addition to its true capsule, a sheath derived from the neighbouring fasciæ. The anterior and posterior layers of the sheath remain distinct at the medial border of the kidney and are prolonged, the one in front of, and the other behind the renal vessels. The two layers remain separate also for some distance below the inferior pole of the kidney, and it is into this downward extension of the fascial compartment that the kidney descends in the condition known as **movable kidney.** Above and laterally the sheath joins the fascial lining of the diaphragm and transversus muscles respectively. Outside the perinephric fascia is a second layer of fat sometimes spoken of as the **paranephric fat.**

When the inferior pole of the kidney receives a special blood-supply, either directly from the aorta, or from the renal artery, the abnormal vessel may, by passing either in front or behind the superior part of the ureter, cause the latter to be so kinked over the vessel as to cause a secondary hydronephrosis.

Brodel has shown that the branches of the renal artery are distributed to the cortex of the kidney in an anterior and a posterior group; hence, in splitting the kidney substance to reach the renal pelvis, the incision should be made along the frontier line between the two vascular areas, viz., about half an inch behind and parallel to the lateral border of the kidney.

The **ureters**, 10 in. (25 cm.) in length, lie behind the peritoneum covering the psoas major muscles; they descend almost vertically in the umbilical region $1\frac{1}{2}$ in. from the median plane. At the level of the intertubercular plane they lie in front of the termination of the common iliac arteries, and then pass down into the pelvis minor, in front of the hypogastric arteries.

The diameter of the ureter is not uniform. Its intra-vesical portion has the smallest lumen, and it is here that calculi are most likely to be impacted. A second narrowing occurs at or a little below the pelvi-ureteral junction, and a third where it crosses the brim of the pelvic minor.

The ureter possesses a well-developed muscular wall so that it is well adapted for suturing, while its rich blood-supply favours rapid healing. Its abdominal portion is supplied by the renal and internal spermatic arteries; its pelvic portion by the superior vesical, the inferior vesical, and the middle hæmorrhoidal arteries. By their anastomoses they form a continuous and somewhat tortuous chain which is generally visible beneath the peritoneum along the whole course of the tube.

The outline of the pelvis of the kidney and the relations of it and the ureter to the skeleton have assumed an additional importance now that they can be demonstrated graphically by the X-rays after injecting them with *a colloidal solution of silver.* The shape of the normal pelvis and the arrangement of its primary and secondary calyces vary considerably. The shadow is situated opposite the tips of the transverse processes of the first and second lumbar vertebræ, the upper calyces generally overlapping a portion of the twelfth rib. Normally the pelvis can contain about 7 c.c. of fluid without discomfort to the patient. The wall of the pelvis, like that of the ureter, is very elastic, so that it is capable of great

distension in cases of gradually increasing urinary obstruction; and for the same reason incisions into either of these structures heal rapidly because the edges of the wound fall into apposition. To avoid branches of the renal vessels incisions into the pelvis should be made horizontally through its posterior wall.

The radiographic shadow produced by an opaque catheter in the ureter crosses the tips of the transverse processes of the four lower lumbar vertebræ and then descends opposite the sacro-iliac joint to its inferior extremity; from here the shadow curves laterally almost parallel to that of the pelvic basin and terminates at the vesical orifice, which is usually opposite a point a little above and internal to the pubic tubercle. Laterally the shadow reaches almost to that caused by the ischial spine. The ureter is occasionally double throughout, or it may be bifid above or below. When the kidney is prolapsed, the abdominal portion of the ureter is more or less tortuous.

In reading skiagrams with a view of ascertaining the presence or absence of calculi in the abdominal portion of the urinary tract, Hurry Fenwick makes use of a line projected vertically upwards from the highest part, *i.e.* the centre, of the iliac crest to the twelfth rib. As this line corresponds to the lateral limit of the kidney, it follows that a "calculus shadow" close to the medial side of this line will generally occupy one of the calyces and be situated, therefore, towards the cortex, while if the shadow be situated close to the tips of the transverse processes of the vertebræ, the calculus will usually be found either in the pelvis of the kidney or in the abdominal portion of the ureter.

Pancreas.—The *head of the pancreas* occupies the curve of the duodenum, and lies in the lowest part of the right half of the epigastric region, on a level with the second lumbar vertebra. The *neck*, which crosses the median plane opposite the fibro-cartilage between the first and second lumbar vertebræ, lies in the trans-pyloric plane, while the body lies immediately above that plane. The *tail* lies in the left hypochondriac region. The relations of the pancreas to the transverse mesocolon and to the neighbouring viscera have already been sufficiently referred to.

After opening the abdomen in the median line, the pancreas is best exposed by passing through the gastro-colic ligament; access to the organ through either the hepato-gastric ligament or the transverse mesocolon is more limited and therefore less satisfactory.

A pancreatic cyst gives rise to a tumefaction of the abdomen either in the epigastric or in the umbilical region, depending on whether it pushes the hepato-gastric ligament before it and develops between the liver and stomach, or whether it extends forwards below the stomach. In severe contusions of the abdomen the pancreas may be ruptured against the vertebral column.

Vessels of the Abdomen.—The commencement of the **abdominal aorta** and the **cœliac artery** are situated two fingers'-breadth above the transpyloric plane. The **superior mesenteric** artery arises a finger's-breadth above the transpyloric plane, the **renal arteries** a finger's breadth below it. The **inferior mesenteric artery** arises mid-way between the transpyloric and the intertubercular plane—that is to say, about 1 in. above the level of the umbilicus. The **abdominal aorta** bifurcates in, or a little to the left of, the median plane, on a level with the highest part of the iliac crest, and about $\frac{3}{4}$ in. below the level of the umbilicus.

The **inferior vena cava** lies immediately to the right of the aorta; its most important surgical relation is the right ureter, which lies close to its right side.

The **common** and **external iliac arteries** may be mapped out by drawing a line, curved slightly laterally, from a point opposite the bifurcation of the aorta to a point midway between the superior anterior iliac spine and the pubic symphysis: the superior third of this line corresponds to the common iliac, the inferior two-thirds to the external iliac.

In ligaturing the common iliac artery, or the superior part of the external iliac, the close relation of the ureter and the ovarian vessels must be borne in mind, while in ligaturing the inferior part of the external iliac it is the internal testicular vessels and the ductus deferens which have to be avoided.

The **common iliac veins** lie mainly to the right of the corresponding arteries, the

left vein, however, crossing behind the right artery to join its fellow to form the inferior vena cava.

The fact that the left common iliac vein passes *behind* the right common iliac artery to reach the vena cava would seem to afford a sufficient explanation for the much greater frequency with which thrombosis of the femoral vein is met with on the left side as compared with the right side.

The great vessels upon the posterior abdominal wall, along with the adjacent lymph vessels and glands, lie in the tela subserosa, and therefore within the general fascial envelope of the abdomen. Abscesses originating from the retro-peritoneal lymph glands are, therefore, like perinephric abscesses, extra-peritoneal but intra-fascial; abscesses of vertebral origin, whether lumbar, iliac, or psoas, are, on the other hand, extra-fascial. Abscesses connected with the vermiform process are primarily intra-peritoneal; occasionally they ulcerate through the parietal peritoneum and burrow in the extra-peritoneal fat.

THE MALE PERINEUM.

The male perineum is a heart-shaped space, the osseous boundaries of which are the same as those which form the inferior aperture of the pelvis. A line drawn transversely across the perineum between the anterior part of the tuberosities of the ischium crosses the median plane, immediately in front of the anus, and divides the space into an anterior or urogenital triangle and a posterior or rectal triangle.

The **urogenital triangle** is subdivided into a superficial and a deep compartment by the inferior fascia of the urogenital diaphragm; in the **superficial compartment** is the root of the penis, which gives rise to a longitudinal fulness upon the surface. Anteriorly, the surface of the urogenital triangle is continued on to the scrotum, whilst laterally a distinct groove separates it from the medial surface of the thighs. The **central point of the perineum** (common tendon of the perineal muscles) is continuous with the centre of the base of the fasciæ of the urogenital diaphragm, and lies a finger's-breadth in front of the anus. Immediately in front of it, and about 1 in. from the centre of the anus, is the posterior edge of the **bulb** of the **corpus cavernosum urethræ**. The *superficial compartment* of the urogenital triangle is bounded below by the **perineal fascia of Colles**, which is attached posteriorly to the base of the fascia of the urogenital diaphragm, and laterally, on each side, to the margins of the pubic arch. Anteriorly, the fascia of Colles passes on to the scrotum, the penis, and spermatic funiculi, to become continuous with the **fascia of Scarpa** upon the anterior surface of the abdomen.

When the urethra is ruptured below the inferior fascia of the urogenital diaphragm, the course of infiltration of the extravasated urine is determined by these attachments; at first, therefore, the urine is confined within the superficial compartment, but gradually travels forwards, under the fascia of Colles, on to the inferior part of the anterior abdominal wall; it is prevented from passing into the front of the thigh by the attachment of Scarpa's fascia to the fascia lata, a little distal to the inguinal ligament.

The **deep compartment** of the urogenital division of the perineum corresponds to the interval between the inferior and superior fasciæ of the urogenital diaphragm. The most important structures which this compartment contains are the membranous part of the urethra, the bulbo-urethral glands, the internal pudendal vessels, and the artery to the bulb.

The **membranous part of the urethra** lies one inch behind the inferior border of the pubic symphysis. When this division of the urethra is ruptured, the extravasated urine, after filling the deep compartment, may reach the superficial compartment by bursting through the inferior fascia of the urogenital diaphragm where the vessels pierce it; or it may penetrate the superior fascia, infiltrate the perivesical connective tissue and the space of Retzius, and ultimately ascend on the anterior abdominal wall between the fascia transversalis and the parietal peritoneum.

The **bulbo-urethral glands**, which lie immediately behind the membranous part of the urethra, are overlapped by the bulb of the urethra, from which they are separated by the inferior fascia of the urogenital diaphragm. The **internal pudendal**

artery lies just within the margin of the pubic arch. The **artery to the bulb** runs transversely medially $\frac{1}{4}$ in. above the base of the urogenital diaphragm, *i.e.* above the level of a line drawn from the front of the tuberosities to the central point of the perineum.

The **male urethra** measures about eight inches from the external to the internal orifice; the narrowest portion is at the external orifice; a second narrowing occurs at the urogenital diaphragm. It is behind these constrictions that a calculus is liable to become impacted. The *most dependent part* of the urethra is the bulbous portion, and it is in this situation that an organic stricture is most frequently met with. The membranous part of the urethra, situated between the two fasciæ of the urogenital diaphragm, is surrounded by the sphincter urethræ membranaceæ muscle, which, when thrown into spasm, may firmly grip an instrument as it is passed into the bladder. *Rupture of the urethra* from a fall on the perineum generally involves the bulbous portion. A *false passage* made during the passage of an instrument generally traverses the floor of the urethra at the urogenital diaphragm; to prevent this the point of the instrument should always be directed upwards, and the handle at the same time depressed as soon as the instrument is felt to encounter the resistance of the inferior fascia of the urogenital diaphragm. When the *prostate is hypertrophied* the prostatic part of the urethra is elongated, and the internal orifice may look directly forwards, while if the lateral lobes are unequally enlarged it may deviate laterally. Patients with prostatic hypertrophy are seldom able to empty the bladder completely, on account of the dependent well which exists behind the prostate.

From the clinical point of view surgeons speak of an "anterior urethra," situated distal to the membranous portion, and a "posterior urethra," situated proximal to it. While the anterior urethra is the least sensitive portion of the canal, the posterior urethra is highly sensitive and more vascular; and when its mucous membrane is injured toxic agents may be rapidly absorbed by the abundant blood-vessels and lymphatics of its submucous tissue. The anterior urethra is shut off from the posterior urethra by the tonic contraction of the sphincter muscle of the membranous urethra.

Viewed with an endoscope the mucous membrane of the anterior urethra is seen to be smooth and glistening, and to have a pale yellowish-pink colour. The longitudinal row of small pit-like openings on the dorsal wall and the orifices of the lacunæ and mucous glands can be investigated. The mucous membrane of the posterior urethra is of a redder colour. The opening of the utriculus prostaticus is seen as a small slit-like orifice on the most prominent part of the elevation caused by the crista urethralis, while immediately to either side of it is the minute orifice of the ejaculatory duct. At the floor of the sulcus on each side of the crista are the minute openings of the majority of the prostatic ducts.

Cystoscopic Examination of the Bladder.—On making a cystoscopic examination of the bladder special attention is paid to the **trigone**, as most of the pathological lesions are associated with this region. At its anterior angle is the **internal urethral orifice**, while at its postero-lateral angles are the small oblique slit-like **orifices of the ureters**, surrounded by a very slight lip-like elevation of the mucous membrane. At the base of the trigone the mucous membrane is raised into a smooth *transverse ridge* which stretches between the ureteric openings, with a slight forward convexity. The elevation is caused by a bundle of transverse muscular fibres, continuous with the longitudinal fibres of the ureters. The distance of the ureteric orifices from one another is rather more than an inch, while their distance from the internal urethral orifice is slightly less than an inch.

The urine is ejected into the bladder intermittently at intervals of a minute or so. During each ejection the ureteric orifice is seen to pucker up, and as it relaxes the gush of urine takes place in the form of a characteristic whirl "resembling an injection of glycerine into water." The **mucous membrane** of the trigone is closely connected with the subjacent muscular wall, so that it presents a smooth appearance; whereas over the rest of the bladder it is thrown into folds owing to the looseness of the submucous tissue. Further, the mucous membrane of the trigone presents a pink injection, while over the rest of the bladder it is of a pale straw

colour. This contrast is due to the difference in the arrangement of the blood-vessels; over the trigone they are larger, more numerous, and form a close network; hence, when this surface is inflamed, the congested vessels form a continuous vascular layer. Over the rest of the bladder one sees, here and there in the mucous membrane, small segments of fine vessels giving off a cluster of short branches, the finer anastomoses of which are not visible when the mucous membrane is healthy.

The form and shape of the trigone in women may be distorted by prolapse of the bladder, by alterations in the size and position of the cervix, and by the presence of fibroids. In the male, distortion is usually due either to the enlargement of the prostate or to disease of the vesiculæ seminales.

When the normal bladder is comfortably filled, the bladder walls appear almost smooth, but when the bladder contracts the delicate muscular trabeculæ become visible through the mucous membrane. When the bladder is hypertrophied as the result of urinary obstruction the muscular trabeculæ become greatly hypertrophied, and stand out prominently, even when the bladder is full. The spaces between the trabeculæ may become so deeply pitted as to lead to the formation of little pockets, known as **false diverticula**.

THE PROSTATE.

The operation of *prostatectomy* has proved so successful in removing urinary complications associated with enlargement of the **prostate** that a fresh impetus has been given to the study of the anatomy of the gland from the surgical point of view. With the body erect the **base** of the prostate lies in a horizontal plane at the level of the middle of the symphysis pubis, while its **apex** lies $\frac{1}{2}$ in. behind and below the sub-pubic angle. It follows, therefore, that the vesical orifice and the base of the prostate are within easy reach of the finger introduced through a supra-pubic cystotomy incision. The **anterior surface** of the prostate lies about $\frac{3}{4}$ in. behind the pubes, to which it is connected by the pubo-prostatic ligaments. Above those ligaments is the *space of Retzius*, occupied by fatty tissue which passes upwards in front of the anterior wall of the bladder, between the umbilical arteries, as far as the umbilicus, while laterally it extends on each side, between the peritoneum and pelvic fascia, as far back as the hypogastric arteries. The **posterior surface** of the prostate is related to that part of the rectal ampulla immediately above the anal canal, and is therefore accessible to palpation *per rectum*. Between the rectum and the posterior part of the sheath of the prostate (formed by the recto-vesical layer of pelvic fascia) is a loose cellular interval, which is taken advantage of in the operation of excision of the rectum, and in exposing the posterior surface of the prostate in the operation of perineal prostatectomy. The **lateral surfaces** of the prostate cannot be felt through the rectum; they are related to the anterior or pubo-rectal fibres of the levatores ani, from which they are separated by the lateral portion of the fascial envelope of the gland.

The *prostate substance* is made up of branching tubular glands supported by a fibro-muscular stroma. The gland tissue is most abundant in the posterior and lateral aspects of the organ; anteriorly the stroma is more abundant and extends backwards from the capsule to the urethra to form a sort of anterior commissure. By the term "*capsule*" of the prostate is understood the immediate or proper envelope of the gland; this envelope consists of parallel layers of fibro-muscular tissue, continuous with, and forming part of, the stroma of the organ. In some instances it is so thin that the gland tissue reaches almost to its surface, while in other instances it is so thick as to deserve to be regarded as forming the cortical portion of the gland. By the term "*sheath*" of the prostate is meant the fibrous envelope derived from the pelvic fascia; the veins of the *pudendal plexus* lie between its lamellæ.

In what is known as "**senile**" **hypertrophy** of the prostate the organ may be uniformly enlarged, or the enlargement may affect chiefly one or other of the lateral lobes, one or both of which may enlarge more particularly in an upward direction so as to project into the bladder. This intra-vesical overgrowth may take the form either of a more or less pedunculated projection, situated immediately behind, or somewhat lateral to, the

internal urethral orifice, or it may surround the orifice to form a prominent ring-like elevation. As the intra-vesical growth enlarges, it makes its way towards the bladder within the ring of the sphincter vesicæ, and, having pushed before, or separated, the internal longitudinal fibres of the bladder, it comes ultimately to be separated from the cavity of the bladder by mucous membrane only. In the operation of *supra-pubic prostatectomy* the true capsule of the prostate is at once reached by simply tearing through the mucous membrane immediately behind the vesical orifice. By keeping close to the capsule, the entire organ, including the capsule, may be enucleated from its sheath. As the latter is markedly thicker and denser in the hypertrophied than in the normal prostate, this enucleation can be accomplished without injuring the veins of the pudendal plexus. As a rule, the only part where any difficulty in the enucleation is encountered is anteriorly, where the capsule is more intimately connected with the sheath by the interposition of a layer of striated longitudinal muscular fibres which pass from the urethra to be continuous with the outer longitudinal fibres of the bladder. In "total" prostatectomy, practically the whole of the prostatic urethra is removed along with the gland. In some instances, instead of removing the entire prostate and its capsule along with the prostatic urethra, the surgeon, by working within the capsule, is able to enucleate each lateral glandular mass either separately or united to its fellow in the form of a horse-shoe shaped mass, the urethra and the anterior commissure being left more or less intact. The cavity, which is left behind after the removal of the prostate, at once contracts owing to the approximation of the bladder and rectum antero-posteriorly, and of the levatores ani at the sides.

In perineal prostatectomy the posterior surface of the prostate is exposed by making a horse-shoe shaped incision with the convexity reaching forwards to a point immediately behind the bulb; at the sides, the incision sinks into the ischio-rectal fossæ, its extremities ending at the anterior part of the ischial tuberosities. After reflecting the skin and subcutaneous tissue, the incision is carried through the central point of the perineum.

The bulb, the superficial transverse perineal muscles, and the inferior fascia of the urogenital diaphragm are now drawn forwards, and the fibres of the recto-urethral muscle (which connect the anterior wall of the rectal ampulla with the sphincter urethræ) are divided; this allows the anal canal and the inferior end of the rectum to be retracted backwards. The dissection is now carried in a forward direction, between the anterior borders of the levatores ani, towards the prostate, so as to strike the loose non-vascular space which intervenes between the posterior part of the prostatic sheath and the thin fascia outside the muscular wall of the rectum. The posterior surface of the prostate, covered by its true capsule, is reached by incising the fascial sheath. The prostate, along with its true capsule and the urethra, may either be enucleated entire from the sheath, or the true capsule may be incised as well as the sheath, and the adenomatous masses removed separately. The operation is greatly facilitated by pulling the prostate down into the wound by a special retractor (Young) inserted into the bladder through a median incision into the floor of the membranous part of the urethra.

The **epididymis**, which can be felt, as an elongated curved body applied vertically to the posterior margin of the testis, is especially involved in gonorrhœal and tubercular infections of the testis. Occupying the posterior part of the spermatic funiculus is the **ductus deferens**, which, when grasped between the finger and thumb, feels like a piece of whip-cord. The spermatic veins form a plexus in the substance of the funiculus, known as the **pampiniform plexus**; a varicose condition of these veins gives rise to the condition known as *varicocele*. In operating for varicocele the veins are reached by dividing, in succession, all the coverings of the funiculus; the deepest covering, viz., the internal spermatic fascia, derived from the fascia transversalis, forms a well-marked fibrous envelope which immediately surrounds the veins and other constituents of the funiculus. Besides the internal testicular artery, the testis receives its blood-supply from the artery accompanying the ductus deferens and from the external testicular branch of the inferior epigastric.

The marked swelling which attends *œdema and hæmatoma of the scrotum* is due to the loose and delicate character of the cellular tissue which occupies the space between the dartos muscle and the subjacent membrane derived from the inter-columnar fascia.

The **anus** is situated in the rectal division of the perineum about $1\frac{1}{2}$ in. in front of and below the tip of the coccyx. The skin around the orifice is pigmented and thrown into radiating folds. The painful linear crack or ulcer, known as *fissure of*

the anus, generally occupies one of the furrows at the posterior margin of the anus. The skin of the anus is provided with large sebaceous and sweat glands which are occasionally the site of small and very painful anal abscesses.

On making a *rectal examination* it will be observed that the finger, before it reaches the cavity of the rectum, traverses the narrow or sphincteric portion of the rectum, appropriately named by Symington the **anal canal**. This canal, which is directed from below upwards and forwards, extends from the anal orifice to the ampulla of the rectum; it is from one to one and a half inches in length; its upper end is on a level with the medial borders of the pubo-rectal portions of the levatores ani.

External hæmorrhoids are developed from the anal folds situated outside the white line corresponding to the muco-cutaneous junction; *internal piles* are developed from the veins of the mucosa at the upper part of the anal canal.

In the superior half of the anal canal are the rectal **columns of Morgagni**. According to Ball, fissure of the anus is generally caused by the tearing downwards of one of the posterior **rectal sinuses** (Fig. 1088) during the passage of a scybalous mass.

According to Birmingham, the pubo-coccygeal fibres of the levator ani close the superior part of the anal canal, whilst the external sphincter closes the remaining part. The internal sphincter, according to the same author, acts probably as a detrusor, its use being to empty the anal canal completely after the passage of the fæcal mass.

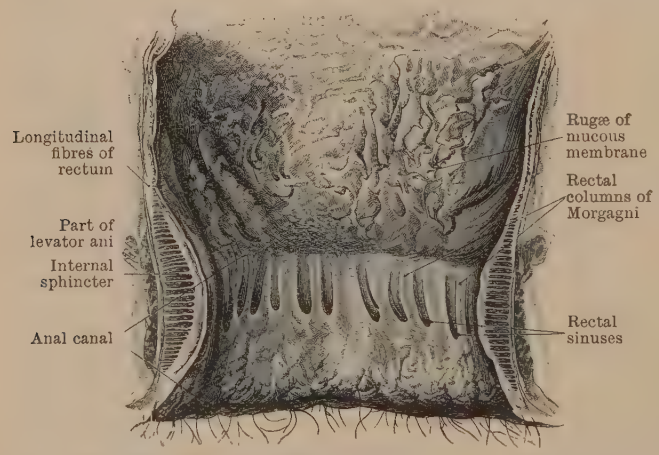

FIG. 1088.—THE INTERIOR OF THE ANAL CANAL AND INFERIOR PART OF THE RECTUM.

Showing the rectal columns of Morgagni and the rectal sinuses between their inferior ends. The columns were more numerous in this specimen than usual. (From Birmingham.)

Ischio-rectal Fossa.—The apex of the **ischio-rectal fossa** (Fig. 1089), formed by the attachment of the inferior fascia of the pelvic diaphragm (anal fascia) to the obturator portion of the parietal pelvic fascia, is directed upwards towards the pelvis, and lies 2½ in. from the surface. The medial wall of the fossa is bounded by the levator ani and coccygeal muscles covered by the inferior fascia of the pelvic diaphragm (Fig. 1089); the lateral wall by the obturator internus muscle covered by the obturator fascia. An *abscess in the ischio-rectal fossa* should be opened early, otherwise it is liable to burst through the medial wall into the rectum; should it open also upon the skin surface a complete "*fistula in ano*" is formed. When a "fistula in ano" results from the bursting of a submucous abscess of the anal canal the track of the fistula runs either medial to or through the fibres of the internal and external sphincter muscles, and the external or skin opening is, as a rule, close to the anus, while the internal opening is generally within the upper end of the anal canal. Occasionally the ischio-rectal abscess perforates the levator ani towards the apex of the fossa; it then burrows into the peri-rectal cellular tissue of the pelvis, and opens into the ampulla of the rectum. In other cases, again, the abscess starts in the peri-rectal tissue internal to the levator ani, and either bursts into the rectal ampulla or through the levator ani into the ischio-rectal fossa, and so reaches the surface. Or the pus may burrow between the rectum and coccyx, whence it may pass outwards through the greater sciatic foramen, behind the parietal pelvic fascia, into the buttock; or, by piercing the visceral layer of the pelvic fascia, may reach the tela subserosa of fatty tissue of the pelvis and ascend in it to form an iliac abscess.

The *lymph* vessels from the skin of the anus pass along the perineo-femoral folds to the most medial glands of the groin, both superficial and deep subinguinal. According to Poirier and Cunéo, those from the region of the white line end in the hypogastric glands which lie in front of the hypogastric artery, while those which issue from the mucous membrane of the upper part of the anal canal and the rectum proper traverse a few minute glands (ano-rectal glands of Gerota) placed between the muscular and fibrous coats of the rectum, along the superior hæmorrhoidal vein and its two branches, and pass thence to the sacral glands which lie internal to the anterior sacral foramina.

Digital Examination of Rectum.—In making a *rectal examination* the finger

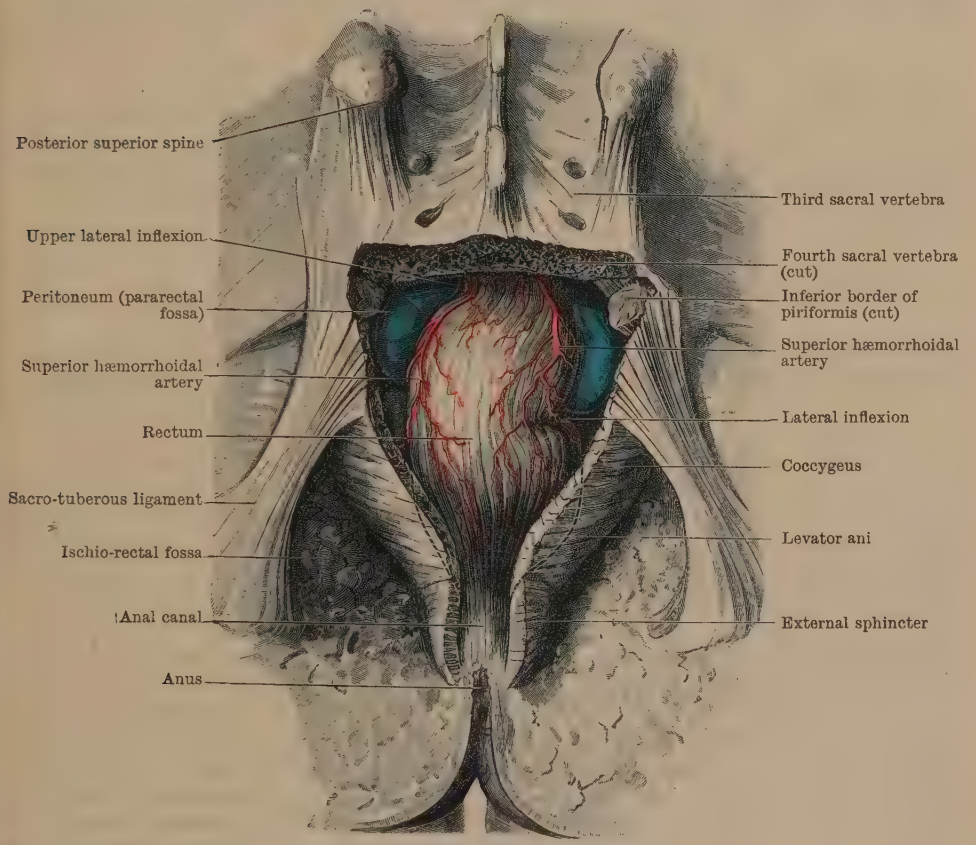

FIG. 1089.—THE RECTUM FROM BEHIND.

The sacrum has been sawn across through the 4th sacral vertebra, and its inferior part removed with the coccyx. The posterior portions of the coccygei, levatores ani, and of the external sphincter have been cut away. The "pinching in" of the inferior end of the rectum by the medial edges of the levatores ani, resulting in the formation of the flattened anal canal, is suggested in the illustration, which has been made from a formalin-hardened male body, aged thirty. The lateral inflexions of the rectum, corresponding to Houston's rectal valves, are also shown. (From Birmingham.)

should be carried forwards from the tip of the coccyx so as to enter the anus from behind. The finger is then gently pressed upwards and slightly forwards through the sphincteric region, in the axis of the anal canal, until it reaches the cavity of the rectum, the inferior part of which is dilated to form the ampulla. The transverse folds of the rectum or valves of Houston, three in number, project into the cavity of the bowel in the form of prominent crescentic shelves, which are produced by the three permanent or true flexures into which the rectum is thrown (Birmingham); the inferior valve, which may be sufficiently prominent to impede the passage of the finger, must not be mistaken for a pathological condition. An exaggerated development of one of these folds in the fœtus is the main factor in the causation of the condition known as *megalocolon* or *Hirschsprung's disease*. The condition is aggravated by the formation of a lateral pouching of the bowel opposite the valve. When the pouch becomes distended with fæcal matter the valve is

pressed against the opposite wall of the bowel and the passage is closed. The mechanism is very similar to that which occurs in congenital hydronephrosis due to an abnormally high and therefore lateral attachment of the ureter to the pelvis of the kidney. Through the anterior wall the finger can palpate from below upwards the bulb of the urethra, the membranous part of the urethra, the bulbo-urethral glands (when inflamed and enlarged), the apex and lateral lobes of the prostate, the vesiculæ seminales, and the external trigone of the bladder. With the left forefinger in the rectum, an instrument passed into the bladder can be distinctly felt as it traverses the membranous urethra; as it lies in the prostatic urethra it is separated from the finger by the prostate. Hence, when a *false passage* is made through the bulbous or membranous portion of the urethra, the instrument, if pushed onwards towards the bladder, will be felt immediately outside the rectum between it and the prostate. In the child, owing to the rudimentary condition of the prostate, the instrument is distinctly felt close to the rectum, as it lies in the prostatic as well as in the membranous portion of the urethra. When the prostate is not enlarged the tip of the finger can just reach the external trigone, which is most distinctly felt when the bladder is full. The vesiculæ seminales, indistinctly felt when healthy, may be readily palpated when enlarged and indurated from disease. Through the side wall of the rectum may be palpated the ischio-rectal fossa, the bony wall of the pelvis minor, and, when enlarged, the hypogastric lymph glands; through the posterior wall the hollow of the sacrum and coccyx, and the lymph glands lying in the retro-rectal cellular tissue.

In the child rectal examination enables one to palpate, in addition to the structures in the cavity of the pelvis minor, those which occupy the lower segment of the abdomen. When the bladder is empty even a small calculus can be readily felt by recto-abdominal palpation.

The distance of the apex of the **recto-vesical pouch** of peritoneum from the anus varies considerably, according to the degree of distension of the bladder and rectum; when both are empty it reaches to about 2 in. from the anus; when both are distended it is at least one inch higher (Fig. 1089).

Examination by Sigmoidoscope.—In introducing the sigmoidoscope into the pelvic colon the direction of the anal canal and the curve of the rectum must be borne in mind; as the instrument traverses the anal canal it must be directed forwards as well as upwards, after which it is pushed onwards, in a backward and upward direction, towards the hollow of the sacrum; while, finally, in order to reach the pelvic colon, it is again directed forwards and a little to the left so as to clear the promontory of the sacrum. The instrument is more difficult to pass in women, on account of the greater abruptness of the curvature of the sacrum in the female as compared with the male.

When examined with the sigmoidoscope the mucous membrane of the rectum is seen to possess a deep red colour, and an excellent view is obtained of the rectal valves of Houston. The most conspicuous fold, known as the **plica transversalis**, projects from the right wall about the level of the recto-vesical peritoneal reflexion, *i.e.* about three inches from the anus. The highest valve, situated at the colo-rectal junction, gives rise to a distinct narrowing which must not be mistaken for a stricture. The pulsations of the left common iliac artery can generally be seen to be communicated to the postero-lateral wall of the pelvic colon about four inches from the anus.

Removal of the Rectum.—In removing the rectum and anal canal for malignant disease, an **incision** is carried round the anus and then upwards and backwards over the coccyx and inferior part of the sacrum. The *ano-coccygeal raphe* is divided longitudinally and the *coccyx* (either alone or along with more or less of the lower part of the sacrum) is excised by dividing the structures attached to its margins, viz., the inferior fibres of the glutæus maximus, the coccygeus, and the sacro-tuberous and sacro-spinous ligaments (O.T. greater and lesser sacro-sciatic). The **parietal pelvic fascia**, here very thin and adherent, is removed along with the bone. The **middle sacral artery** is ligatured. This is now seen, stretching across the floor of the wound, a well-defined sheet of fascia, viz., the rectal layer of the **visceral pelvic fascia**, which is divided longitudinally and stripped to either side off the posterior surface of the rectum; in doing this the branches of the **middle hæmorrhoidal arteries** are ligatured. Anteriorly, the anal canal is detached from the **central point of the perineum**, after which the anterior surface of the rectum is freed from below upwards from the urogenital diaphragm containing the **membranous urethra**, the posterior surface of the **prostate**, the trigone of the **bladder** and the **vesiculæ seminales** and the **ductus deferentes**. This procedure is facilitated by the existence of a cellular interval between the anterior wall of the rectum and the strong

recto-vesical layer of visceral pelvic fascia, which forms the posterior part of the sheath of the prostate, and, higher up, encloses the vesiculæ seminales and ductus deferentes. In order to strike this cellular interspace, the surgeon, after dividing the central point of the perineum transversely, deepens the incision down to the apex of the prostate. In doing this he divides a band of muscular fibres (**recto-urethral muscle**) which passes from the anterior wall of the lowest part of the rectal ampulla to blend with the sphincter urethræ muscle surrounding the urethra at the apex of the prostate. It is these recto-urethral fibres, which, by pulling forwards the ampulla, bring it into close relation with the urethra; hence it is especially at this stage of the operation that great care must be taken not to open into the rectum or to wound the urethra. After exposing the apex of the prostate the next step is to retract the anal canal well backwards and to define the anterior or pubo-prostatic borders of the **levator ani** muscle. These muscles are then divided, on each side, well above their insertion into the rectum. The posterior surface of the prostate, covered with recto-vesical fascia, is now exposed.

By continuing the separation of the rectum upwards in the cellular plane above mentioned, the bottom of the **recto-vesical pouch** of peritoneum is reached; it can usually be stripped for some distance off the rectum, without opening into the peritoneal cavity. In freeing the rectum laterally, bands of connective tissue containing branches of the **middle** and **superior hæmorrhoidal vessels** are divided. If the tumour is situated at the superior part of the rectum, the recto-vesical pouch of peritoneum is freely opened in a transverse direction. The **colo-rectal junction** is then mobilised by dividing the sacral attachment of the **pelvic mesocolon** and securing the superior hæmorrhoidal artery. After dividing the rectum well above the tumour, the opening into the peritoneal cavity is closed by suturing together the anterior and posterior walls of the recto-vesical pouch. If a permanent colostomy has been established, the divided bowel is closed; if not, a sacral anus is made.

FEMALE PELVIS.

On opening the abdomen by a median incision extending from the umbilicus to the pubes, and looking into the pelvis minor from above, after displacing some coils of the small intestine upwards, the **fundus of the uterus**, directed forwards and a little upwards, is seen resting upon the superior surface of the bladder. Behind the uterus is the rectum, and between the two the recto-uterine **pouch of Douglas**, containing the pelvic colon and the inferior part of the ileum. The **ovary** lies a little below the level of the superior aperture of the pelvis minor upon a triangular shelf, bounded in front by the broad ligament, behind and medially by the utero-sacral ligament, and behind and laterally by the pelvic wall. When the vermiform process overhangs the superior aperture of the pelvis minor its tip may come into close relation with the right ovary, a condition which often leads to a difficulty in distinguishing an inflammation of that ovary from appendicitis. The **round ligaments** are seen passing forwards and laterally from the upper parts of the right and left borders of the uterus to the abdominal inguinal rings, which lie immediately in front and to the medial side of the terminations of the external iliac arteries. Inferiorly and at the medial side of the round ligament, as it leaves the pelvis, is the **inferior epigastric artery**. By pulling the uterus upwards the attachments of the **broad ligament** to the floor and side walls of the pelvis are brought into evidence, as also are the utero-vesical and recto-vaginal peritoneal pouches; the former is shallow, while the deepest part of the latter covers the upper fourth of the posterior wall of the vagina, and comes into relation, therefore, with the posterior fornix.

The utero-vesical peritoneal reflexion takes place at the level of the junction of the body of the uterus with the cervix. The anterior wall of the cervix comes into relation, therefore, with the superior part of the base of the bladder, from which, however, it is separated by a layer of loose connective tissue. It is the existence of this cellular plane which enables the surgeon to separate the bladder readily from the uterus in the operation of hysterectomy.

While the anterior wall of the vagina is firmly united to the urethra, its posterior wall, on the other hand, can be readily separated from the rectum, in consequence of the interposition between the two organs of the recto-vaginal fascia.

The **ureter** crosses the brim of the pelvis in front of the bifurcation of the common iliac artery $1\frac{1}{2}$ in. lateral to and a little below the centre of the sacral promontory. The corresponding point on the anterior abdominal wall is at the junction of the lateral and middle thirds of a line joining the anterior superior spines of the ilium.

After crossing the termination of the common iliac artery from lateral to medial side, the ureter dips vertically into the pelvis minor behind the peritoneum covering the hypogastric artery. It then courses medially in the parametric cellular tissue below the base of the broad ligament. In this position it lies a little above the lateral fornix of the vagina, about three-quarters of an inch lateral to the superior part of the cervix uteri; finally, just before it pierces the lateral angle of the bladder, it lies in front of the antero-lateral aspect of the upper part of the vaginal wall.

The relation of the pelvic portions of the ureters are of special importance in the female as their close relation to the cervix uteri and upper part of the vagina renders them liable to injury, more especially in the operation of hysterectomy performed for malignant disease of the uterus.

The **uterine artery**, in the first part of its course, passes downwards and forwards a little anterior and lateral to the ureter. At the level of the orificium internum uteri it takes a medial direction and passes along the inferior border of the broad ligament, and crosses, above and in front of the inferior part of the ureter, from lateral to medial side; it then passes above the lateral fornix of the vagina and finally ascends close to the side of the body of the uterus, and ends by anastomosing with the ovarian artery below the isthmus of the uterine tube.

The **ovarian artery** enters the pelvis minor between the layers of that portion of the broad ligament known as the **ligamentum suspensorium ovarii**; it is here that the vessel may be most readily ligatured in abdominal hysterectomy, and in ovariotomy.

The **lymph vessels** from the inferior part of the vagina pass to the superficial vaginal and sacral glands, while those from the rest of the vagina, from the cervix uteri and from the body of the uterus, pass to the hypogastric, the external iliac, and the sacral glands. The hypogastric glands are situated on the side wall of the pelvis in close relation to the origins of the branches of the hypogastric artery. The sacral glands form a chain along the medial side of the anterior sacral foramina. The lymph vessels from the fundus of the uterus, and from the ovary, terminate in the glands around the aorta.

The external genitals are fully described elsewhere (p. 1306). The **external orifice of the urethra**, surrounded by a slight annular prominence of the mucous membrane, is situated about 1 in. behind the clitoris, immediately above the centre of the base of the vestibule—a smooth triangular area at the anterior part of the vulva, with its sides formed by the labia minora and its base by the anterior margin of the ostium vaginæ. In passing a *catheter* the instrument is directed along the forefinger (introduced just within the ostium vaginæ with the palmar surface towards the symphysis pubis) to the base of the smooth vestibule, where it is tilted slightly upwards so as to bring its point opposite the urethral orifice.

The larger **vestibular glands**, about the size of a bean, are placed on each side of the posterior third of the orifice of the vagina, below the urogenital diaphragm. Their ducts, nearly one inch in length, open posteriorly between the hymen and the posterior commissure (*fossa navicularis*). Abscesses and cysts not infrequently develop in connexion with these glands. The **bulbs of the vestibule** are two piriform collections of erectile tissue situated on each side of the vestibule, between the bulbo-cavernosus muscle and the inferior fascia of the urogenital diaphragm. Rupture of these bodies gives rise to the condition known as *pudendal hæmatocele.*

The **cervix uteri** projects downwards and backwards into the roof of the vagina so as to leave a distinct **fornix** between the two. The relations of the fornix are of so much practical importance that for descriptive purposes it is customary to subdivide it into an anterior, a posterior, and two lateral portions. The **anterior fornix**, which is shallow, is related to the base of the bladder and to the utero-vesical pouch of peritoneum. The **posterior fornix**, which is deeper, extends upwards for some little distance in front of the anterior wall of the lowest part of the pouch of Douglas. The septum between the two is formed merely by the wall of the vagina; hence the readiness with which the pelvis may be drained by puncturing it and pulling a tube through the opening from the pelvis into the vagina.

The **lateral fornix** lies below the medial part of the base of the broad ligament. An incision carried through it would therefore open into the parametric cellular

tissue and would expose the uterine artery as it passes transversely to the uterus, after crossing above and in front of the lower part of the ureters.

Vaginal Examination.—In making a *vaginal examination* the patient should be placed in the dorsal position, with the thighs well flexed; the index-finger of the right hand is now carried along the fold of the buttock towards the median plane, where it will impinge against the posterior aspect of the **introitus vaginæ**, whence it is inserted upwards and backwards into the canal; to render the examination more thorough the middle finger also may be introduced. When the uterus is in its normal position the **vaginal part of the cervix uteri** is felt as a knob-like body projecting downwards and backwards into the upper part of the canal. In nulliparæ the orificium uteri externum is a small transverse slit, whereas in women who have borne children it is larger and more or less fissured. Above and behind the cervix is the **posterior fornix**, which is in close proximity to the **recto-uterine pouch** of Douglas; this pouch, though normally empty, is the frequent site of displaced abdominal and pelvic organs, and collections of intra-peritoneal effusions and exudations. A loaded rectum can be detected through the vagina by the characteristic way in which the contents can be pitted by the finger. In front of the cervix is the shallow **anterior fornix**, through which may be felt the body of the uterus and the base of the bladder, while through the inferior half of the anterior vaginal wall the **urethra** may be detected as a cylindrical, cord-like thickening which may be rolled against the inferior border of the symphysis. The **ureter**, especially if enlarged, can be recognised through the antero-lateral fornix, by compressing it against the pubic bone.

By the *bimanual examination* the pelvic organs are steadied and pushed downwards towards the inferior aperture of the pelvic by the pressure of the left hand applied in the hypogastric region, so that they can be more readily reached and palpated by the finger placed in the vagina with its palmar aspect directed upwards. The **ovary** may be felt as a firm body about the size of the end of the thumb by pushing the fingers well up into the lateral fornix towards the side wall of the pelvis. In health the ovaries are freely movable. The healthy **uterine tubes** cannot, as a rule, be felt per vaginam.

Examination of Interior of Bladder.—The whole of the **interior of the bladder** in the female can be readily seen by reflecting light into it through a speculum introduced into the empty bladder after dilating the urethra. The patient is placed in the genu-pectoral position, so that the bladder may become inflated with air, the coils of intestine being displaced upwards. In the distended condition of the bladder the mucosa has a dull white or straw-coloured appearance, except in the region of the trigone, which shows a pale pink injection. The **ureteral orifices** placed a little more than one inch apart and connected by a slight transverse ridge (inter-ureteric fold), present the appearance of fine oblique slits situated upon small and somewhat injected elevations of the mucosa.

Rectal Examination.—By rectal examination the finger can palpate, from below upwards, the recto-vaginal septum, the cervix uteri, the posterior fornix of the vagina, the apex of the recto-uterine pouch of Douglas, and the body of the uterus. By washing out the rectum and introducing a speculum into the bowel, with the patient in the genu-pectoral position, the rectum becomes inflated with air; the finger can now feel very distinctly the posterior surface of the uterus and the uterine tubes, and by running the finger laterally, along the prominent fold formed by the utero-ovarian ligament, the ovary is also very distinctly felt.

THE BACK.

Median Line of the Back.—In the median line of the back is the **vertebral furrow**, which is deepest in the inferior thoracic and superior lumbar regions, where the sacro-spinales muscles are most prominent. Over the superior sacral region, where the sacro-spinales muscles are tendinous, is a flattened area forming an equilateral triangle, the angles of which correspond respectively to the posterior superior spines of the two iliac bones and the third sacral spine. The **vertebral spines** can be palpated at the bottom of the vertebral furrow; they become more distinct when the vertebral column is flexed, and, as pointed out by Holden, they become mapped out by reddened areas when friction is applied along the furrow. The identification and counting of the spines will be facilitated if it is remembered that the first thoracic is more prominent than the vertebra prominens (seventh cervical), that the third thoracic is on a level with the root of the spine of the scapula, the seventh thoracic its inferior angle, the fourth lumbar with the highest part of the iliac crest, and the second sacral with the posterior superior iliac spine.

Lateral Region of the Back.—Above the spine of the scapula is the **supra-scapular region**, which is padded by a thick mass of muscle consisting of the supra-spinatus and levator scapulæ, covered by the superior part of the trapezius; the two latter muscles may be thrown into relief by shrugging the shoulders.

In the **interscapular region** are the rhomboid muscles which are thrown into prominence by bracing back the shoulders.

Below the inferior angle of the scapula the last five ribs can readily be felt lateral to the sacro-spinalis muscle; when the twelfth rib does not reach beyond this muscle, the eleventh rib will be mistaken for it, unless the ribs are counted from above downwards.

The **inferior border of the trapezius** is indicated by a line extending upwards and laterally from the twelfth thoracic spine to the root of the spine of the scapula; the **superior border of the latissimus dorsi** by a line extending from the sixth thoracic spine transversely laterally across the angle of the scapula. Between these two muscles and the inferior part of the vertebral margin of the scapula is a triangular area, the floor of which is formed by the rhomboideus major muscle and the sixth costal interspace.

The lateral border of the **sacrospinalis** is indicated on the surface by drawing a line from a point on the iliac crest $3\frac{1}{2}$ in. (four fingers'-breadth) from the median line, upwards and slightly laterally to the angles of the ribs. The lateral border of the **quadratus lumborum**, which passes upwards and slightly medially, lies a little lateral to that of the sacrospinalis at the crest, and a little medial to it at the twelfth rib.

The anatomy of the muscles and fasciæ which complete the abdominal wall between the last rib and the iliac crest is of great importance in connexion with operations in the **region of the loin**. The space between the last rib and the iliac crest varies greatly according to the length of the rib, and according to the general shape of the chest and slope of the ribs as a whole. As a rule, the **tip of the twelfth rib** lies about two inches vertically above the centre of the iliac crest. From a surgical point of view the costo-iliac space may be said to be limited medially by the lateral edge of the sacrospinalis, and, more deeply, by the tips of the transverse processes of the lumbar vertebræ, while laterally it is bounded by the posterior free border of the external oblique, and, more deeply, by the line of reflexion of the peritoneum from the colon on to the side wall of the abdomen. The space is roofed over by the latissimus dorsi, except below, where a narrow triangular interval is left between its lateral border and the posterior border of the external oblique, the base of the triangle being formed by the crest of the ilium, a little behind its centre. This triangle, known as the **lumbar triangle of Petit**, represents a weak area through which a lumbar abscess may come to the surface, and through which a lumbar hernia occasionally develops. On removing the latissimus dorsi and the lower part of the thin serratus posterior inferior, another triangle will be exposed, which constitutes a second weak area in the loin; it is bounded above by the last rib, medially by the lateral border of the sacrospinalis, and laterally by the posterior muscular fibres of the internal oblique; the floor of the triangle is formed by the aponeurosis of origin of the transversus abdominis muscle. At the lateral border of the quadratus lumborum this aponeurosis splits into three layers to form two compartments, the anterior enclosing the quadratus lumborum and the posterior the sacrospinalis.

Kidneys.—The superior limit of the kidney is indicated by a line drawn transversely across the loin opposite the eleventh thoracic spine, the inferior limit by a line on a level with the third lumbar spine. The superior extremity reaches to the eleventh rib; the lower, which lies immediately lateral to the tip of the transverse process of the third lumbar vertebra, reaches to within $1\frac{1}{2}$ to 2 in. of the crest of the ilium. About a third of the kidney lies above the inferior margin of the twelfth rib. The left kidney usually lies about $\frac{1}{2}$ in. higher than the right. The most lateral point of the lateral border lies 4 in. from the median plane, while the hilum lies $1\frac{1}{2}$ in. lateral to the median plane in front of the interval between the tips of the transverse processes of the first and second lumbar vertebræ.

The psoas major muscle intervenes between the postero-medial surface of the kidney and the transverse processes, and protects the organ from injury by a blow directed from the front. Between the superior end of the kidney and the eleventh and twelfth ribs is the diaphragm and the posterior costo-diaphragmatic reflexion

of the pleura (Fig. 1074). The relations of the pleura to the last rib have already been considered (p. 1393).

Posteriorly the course of the superior part of the **ureter** may be indicated by a line drawn vertically upwards from the superior posterior iliac spine to the level of the second lumbar spine; the deep guides are the tips of the transverse processes of the second, third, and fourth lumbar vertebræ, covered by the psoas major muscle.

Exposure of Kidney from behind.—In exposing the kidney from the loin, by a **vertical incision** between the lateral border of the sacrospinalis and the free posterior border of the external oblique muscle, the following structures are divided from without inwards: (1) the integuments; (2) the lower fibres of the latissimus dorsi and serratus posterior inferior muscles;

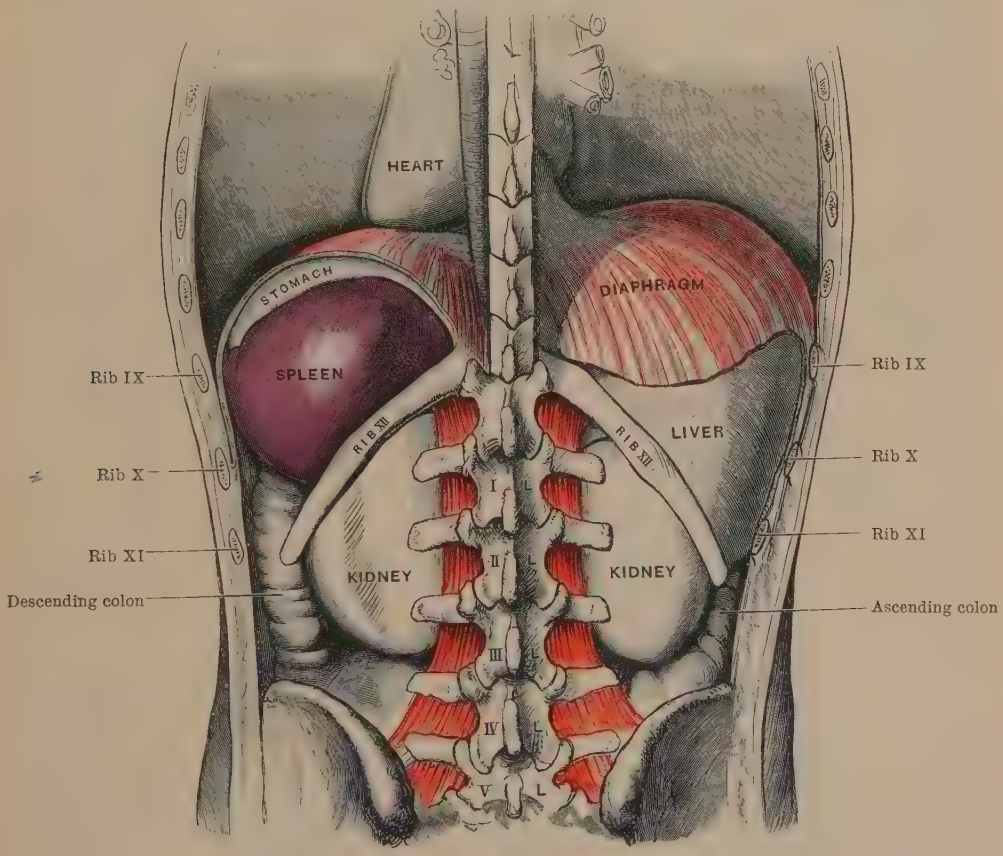

FIG. 1090.—DISSECTION OF THE SPLEEN, LIVER, AND KIDNEYS FROM BEHIND, IN A SUBJECT HARDENED BY FORMALIN INJECTION. (From Cunningham.)

(3) the middle layer of the lumbar aponeurosis, just lateral to the sacrospinalis compartment, and parallel to the lateral fibres of the quadratus lumborum muscles; (4) the anterior layer of the lumbar aponeurosis (which forms the aponeurotic origin of the transversus muscles), and the transversalis fascia; (5) the paranephric fat; (6) the perinephric fascia; (7) the perinephric fat surrounding the true capsule of the kidney. The kidney may be readily mobilised and brought to the surface by shelling it out of its fatty capsule with the finger. In cases of difficulty better access to the renal vessels can be obtained if the incision is made a little nearer the median plane, so as to open into the sacrospinalis compartment. This allows of the muscle itself being retracted medially more efficiently.

In exposing the kidney by an **oblique incision** in the loin, the latissimus dorsi and serratus posterior inferior muscles are divided at the medial part of the wound, while at its lateral part the posterior fibres of the external and internal oblique muscles are divided; next, the aponeurotic origin of the transversus muscle and the transversalis fascia are split so as to expose the extra-peritoneal fat and the peritoneum, as it is reflected from the ascending colon on to the lateral aspect of the abdominal wall. The latter structures are then stripped forwards and medially off the anterior surface of the kidney, until the hilum and renal vessels are reached.

The sacrospinalis and quadratus lumborum muscles are retracted well medially, and it may be necessary to divide the lateral fibres of the quadratus muscle.

The upper part of the ureter is exposed by extending the division of the abdominal muscles still further downwards and forwards into the iliac region. After stripping the peritoneum off the quadratus and psoas muscles, the ureter will be found to cling to the deep surface of the membrane. Care is taken not to injure the internal testicular or ovarian vessels, which cross the ureter superficially, and from the medial to the lateral side. The ureter is surrounded by a quantity of loose cellular tissue, and, owing to an abundance of elastic fibres in its adventitious coat, is very elastic, so that it can be readily pulled up to the surface.

To deliver an enlarged kidney out of the loin, it is generally necessary to prolong the incision upwards so as to divide the lateral lumbo-costal arch; and it may be necessary to divide, fracture, or resect the twelfth rib also. In doing this it is not always possible to avoid opening into the lowest part of the pleural sinus, which descends in front of the medial half of the rib.

In operating on the kidney, the last thoracic, and the ilio-hypogastric and ilio-inguinal nerves, which lie posterior and then lateral to it, must not be injured; the last thoracic nerve should be retracted upwards and laterally, the other two downwards and medially.

A needle passed through the medial extremity of the eleventh intercostal space will transfix the **suprarenal gland.**

The pus of a **perinephric abscess** occupies the fatty layer of the tela subserosa (perinephric fat), and lies, therefore, within the fascial envelope of the abdomen; the pus in a **psoas abscess**, on the other hand, lies external to the fascia. In opening a psoas abscess from behind, a vertical incision is made in the angle formed by the lateral border of the sacrospinalis and the crest of the ilium; in the deeper part of the dissection the surgeon should keep close to the front of the transverse process of the fourth lumbar vertebra.

Diaphragm, Liver, Stomach, and Large Intestine.—Posteriorly the **right arch of the diaphragm** and the right lobe of the liver extend upwards to the level of the angle of the scapula (eighth rib), while the **left arch** and the fundus of the stomach lie one inch lower (eighth interspace); the central tendon reaches up to the eighth thoracic spine. The **right lobe of the liver** is covered posteriorly by the eighth to the twelfth ribs, and is overlapped by the base of the right lung as far as a line drawn horizontally laterally from the tenth thoracic spine; hence, posteriorly, the superior limit of the liver cannot be defined by percussion, and its inferior limit merges into the dulness of the loin muscles and kidney.

The **cardiac orifice of the stomach** lies one inch to the left of the ninth thoracic spine. The cardiac portion, overlapped by the ninth to the twelfth ribs, extends upwards to the level of the eighth thoracic spine, one inch below the inferior angle of the scapula. The **pyloric portion** crosses the median plane opposite the first and second lumbar spines, the **pylorus** itself being situated one inch to the right of the first lumbar spine. The **lesser curvature** lies to the left of and below the tenth, eleventh, and twelfth thoracic spines.

Viewed from behind, the **large intestine**, on both sides, overlaps the lateral border of the kidneys and lies parallel to the lateral border of the sacrospinalis muscles. The peritoneum is reflected from the colon on to the posterior abdominal wall along a line drawn vertically upwards from the centre of the iliac crest. The **left flexure** of the colon, which reaches up to the level of the twelfth thoracic spine and the tenth rib, lies about five inches above the iliac crest. The **right flexure** lies on a level with the first lumbar spine.

Spleen.—The *spleen*, situated in the left hypochondrium, behind the cardiac end of the stomach, is overlapped by the ninth, tenth, and eleventh ribs, the long axis of the organ corresponding approximately to that of the tenth rib. Between the superior third of the spleen and the chest wall (pleura and diaphragm intervening) is the base of the left lung, the inferior margin of which crosses the organ horizontally at the level of the tenth thoracic spine. The costo-diaphragmatic reflexion of the pleura reaches down as far as the inferior angle of the spleen. The superior limit of the organ cannot therefore be defined by percussion; and unless enlarged, or displaced downwards, the spleen cannot be punctured from behind without traversing the pleural as well as the peritoneal cavity.

Of the *three angles* of the spleen, the *posterior or vertebral* lies at the same level as the inferior margin of the lung, $1\frac{1}{2}$ in. lateral to the tenth thoracic spine. The *inferior angle* lies opposite the eleventh intercostal space on a level with the first lumbar spine, in a line drawn vertically upwards from a point one inch behind the centre of the iliac crest. This angle is situated behind the superior part of the descending colon, immediately lateral to the middle of the lateral border of the

kidney. The *anterior angle* is at the level of the ninth interspace in the mid-axillary line. Having placed a mark on the skin opposite these three angles the organ is mapped out on the surface as follows:—The *posterior margin* is obtained by joining the posterior and inferior angles; this margin, which gives the key to the position of the spleen, will be found to follow the tenth intercostal space. The short *inferior margin* corresponds to a line joining the anterior and the inferior angles; it is related to the left flexure of the colon. Commencing at

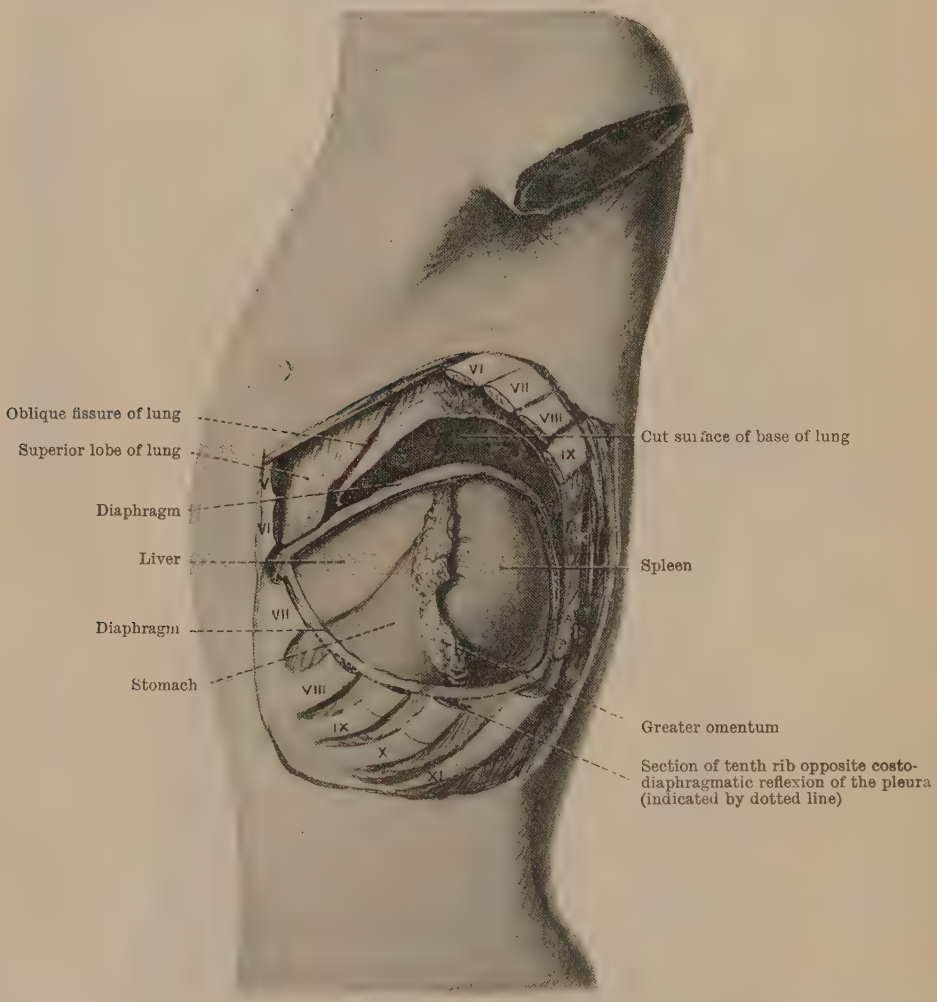

FIG. 1092.—DISSECTION OF THE LEFT HYPOCHONDRIUM TO SHOW THE RELATIONS OF THE SPLEEN TO THE SIDE WALL OF THE CHEST, THE DIAPHRAGM, AND THE ADJACENT VISCERA. In addition to the portions of ribs, there has been removed a part of the base of the left lung, and a window has been made in the diaphragm almost down to the level of the costo-diaphragmatic reflexion of the pleura.

the vertebral angle, the *anterior margin* is at first arched, the summit of the arch reaching to the level of the upper border of the ninth rib in the scapular line; thence it is continued downwards and forwards across the posterior axillary line as the "anterior crenated border" to the anterior angle. The upper arched portion lies parallel to and about one inch below the highest part of the fundus of the stomach. The only parts of the splenic outline which can be defined by percussion are the lower crenated part of the anterior margin, the anterior angle, and the short postero-inferior or colic border; and it is these parts which may be felt below the costal margin when the organ is considerably enlarged.

TABLE INDICATING THE LEVEL OF THE MORE IMPORTANT STRUCTURES IN RELATION TO THE SPINES OF THE VERTEBRÆ.

Spines of Vertebræ.	Origins of Spinal Nerves.	Level of other Structures.
1 Cervical	2 Cervical	Soft palate.
2 „	3 „	Isthmus of fauces.
3 „	4 „	Upper part of epiglottis.
4 „	6 „	Vocal folds (O.T. cords).
5 „	7 „	Conus elasticus.
6 „	8 „	Arch of thoracic duct. Commencement of trachea and œsophagus.
	1 and 2 Thoracic	Inferior end of cervical enlargement of spinal medulla. Inferior cervical ganglion of sympathetic. Apices of lung.
1 Thoracic	3 „	Summit of arch of subclavian artery.
2 „	4 „	Medial angle of scapula. Just above level of highest part of arch of aorta. Jugular notch.
3 „	5 and 6 „	Root of spine of scapula. Arch of vena azygos. Highest part of inferior lobes of lungs. Termination of arch of aorta. Bifurcation of trachea. Lower limit of superior mediastinum. Angulus sterni.
4 „	6 „	Commencement of descending thoracic aorta. Bronchi. Superior limit of heart.
5 „	8 „	Centre of root of lung. Mitral orifice.
6 „	9 „	Tricuspid orifice.
7 „	10 „	Inferior angle of scapula. Orifice of inferior vena cava. Right arch of diaphragm.
8 „	11 „	Lowest limit of heart. Left arch of diaphragm. Fundus of stomach. Xiphi-sternal articulation.
9 „	12 Thoracic and 1 Lumbar	Superior limit of spleen.
10 „	2 Lumbar	Cardiac orifice of stomach. Upper end of lumbar enlargement. Lower border of lung, posteriorly. Vertebral angle of spleen (apex of spleen). Superior end of left kidney. Lesser curvature of stomach.
11 „	3 and 4 „	Lower limit of pleura at vertebral column. Superior end of right kidney. Suprarenal gland. Body of pancreas. Lesser curvature of stomach.
12 „	1, 2, 3 Sacral	Level at which pleura crosses twelfth rib. Inferior end of spleen. Left flexure of colon. Superior part of head of pancreas. Pylorus and pyloric portion of stomach.
1 Lumbar	4 and 5 Sacral	Conus medullaris. Lower limit of pleura (mid-axillary line). Hila of kidneys. Head of pancreas. Right flexure of colon. Portal vein. Descending part of duodenum. Greater curvature of stomach. Bile-duct.

TABLE INDICATING THE LEVEL OF THE MORE IMPORTANT STRUCTURES IN RELATION TO THE SPINES OF THE VERTEBRÆ—*Continued.*

Spines of Vertebræ.	Origins of Spinal Nerves.	Level of other Structures.
2 Lumbar . .	...	Commencement of ureters. Lowest part of head of pancreas.
3 „ . .	...	Inferior limit of spinal medulla in child. Inferior ends of kidneys. Horizontal part of duodenum.
4 „ . .	...	Highest part of crest of ilium. Bifurcation of aorta. Umbilicus.
5 „ . .	...	Common iliac arteries. Valve of the colon.
1 Sacral . .	...	Sacral promontory.
2 „ . .	...	Lower end of sub-dural space.
3 „ . .	...	Superior end of gluteal cleft. Inferior limit of sub-arachnoid and sub-dural spaces.

To excise the spleen the abdomen is opened by a vertical incision through the upper half of the left rectus muscle a little lateral to the middle line. The spleen is drawn forwards into the wound after displacing the stomach and transverse colon downwards and to the right. The vasa brevia are secured as they course between the two layers of the gastro-splenic omentum. The large splenic vessels, which form the main pedicle, lie between the two layers of the lieno-renal ligament. Care must be taken not to injure the tail of the pancreas, which not infrequently extends to the left across the lower part of the gastric surface of the spleen as far as its hilum. In a floating spleen its two peritoneal ligaments are elongated to form a distinct pedicle.

Pancreas.—The head of the pancreas lies opposite the last thoracic and first lumbar spines; the tail lies at the same level as the left flexure of the colon, a little above the inferior basal angle of the spleen.

Spinal Medulla.—While the spinal medulla usually ends opposite the inferior border of the first lumbar spine, it may terminate one vertebræ higher or lower; in the infant it reaches to the interval between the second and third lumbar spines. The *cervical enlargement*, which corresponds to the lower four cervical and the first two thoracic segments, ends opposite the seventh cervical spine. The five lumbar segments are opposite the last three thoracic spines. According to Elsberg the fourth cervical segment lies opposite the third cervical spine, the eighth cervical segment opposite the interspace between the fifth and sixth cervical spines, the fourth thoracic opposite the second thoracic spine, the eighth thoracic opposite the fifth thoracic spine, the twelfth thoracic opposite the ninth thoracic spine, the second lumbar opposite the tenth thoracic spine. The sacral segments correspond to the last dorsal and first lumbar spines (see Fig. 435, p. 520).

The nerve roots which arise below those of the first lumbar, and which go to form the cauda equina, are arranged in a right and a left bundle, with a median space between them. The highest roots occupy the most lateral position in the cauda, while the lowest are nearest the filum terminale.

To expose the spinal medulla by the operation of laminectomy the surgeon, after separating the muscles from the spines and laminæ, removes certain of the spinous processes along with their supra-spinous and inter-spinous ligaments. The next step consists in the removal of the necessary laminæ. This is not difficult in the cervical region where they are comparatively slender and do not overlap. In the thoracic region there is more difficulty, owing to the greater breadth of the laminæ and to their imbricated arrangement; in the lumbar region the difficulty arises from the greater depth and thickness of the laminæ. The bleeding comes mainly from (1) the posterior external vertebral veins, which form a plexus dorsal to the vertebral arches, and (2) from the internal vertebral plexus which occupies the fatty tissue between the dura and the spinal canal. After incising the dura mater and arachnoid cerebro-spinal fluid escapes. The anterior and posterior nerve roots are now exposed, and are seen to be separated by the dentate ligament which ends below in a fork-like manner opposite the first lumbar vertebra. As the first lumbar posterior root rests on the "fork," this structure serves as a guide to the nerve (Elsberg). Tumours which arise outside the cord, but within the dura, may be classified as anterior or posterior according as they lie in front of, or behind the dentate ligament. To

reach an anterior tumour it is necessary to divide one of the tooth-like attachments of the ligament, and generally also one, or possibly two, adjacent posterior roots, after which the cord can be displaced backwards and towards the opposite side.

The **sub-dural space** extends down to the level of the second or third sacral spines. In performing the operation of *lumbar puncture* (Quincke) a fine trochar and cannula are introduced into the sub-arachnoid space below the level of the spinal medulla, the puncture being made $\frac{1}{4}$ to $\frac{1}{2}$ in. to one side of the interspinous ligament in the interval between the third and fourth or fourth and fifth lumbar spines. The fourth spine is at the level of the highest part of the crest of the ilium. The instrument should be directed medially towards the median plane and very slightly upwards. In the adult the distance of the dura mater from the surface is from 2 to 3 in., in the infant $\frac{3}{4}$ in.

Owing to the shape and arrangement of the articular surfaces of the vertebræ, dislocations without fracture are practically confined to the cervical region; they are commonest between the fifth and sixth vertebræ. The dislocation may be unilateral, but it is more frequently bilateral and incomplete. In both instances the cord may be only slightly bruised, in which case the paralysis will be only partial. In complete bilateral dislocations the cord is usually completely crushed, and when the lesion is at, or above, the level of the fourth cervical segment (origin of the phrenic nerves) death ensues rapidly from respiratory paralysis.

Fracture-dislocations of the vertebral column are commonest in the lower cervical and thoraco-lumbar regions; that is to say, where the movable cervical and lumbar regions join the more fixed thoracic region. The vertebral column above the injury is generally displaced forwards, so that the spinal medulla is often severely lacerated or completely torn across by the superior end of the portion of the column below the fracture. It is important to remember that, in consequence of the shortness of the spinal medulla as compared with the vertebral column, the origins of the spinal nerves are at a higher level than their exits from the vertebral canal. The distance between origins from the spinal medulla and exits through the intervertebral foramina becomes greater the further down the nerves are, the lowest nerve trunks running almost vertically downwards. The cervical nerves leave the vertebral canal *above* the vertebræ after which they are named (except the *eighth*, which is above the first thoracic vertebra); the thoracic, lumbar, and sacral nerves, on the other hand, leave the canal *below* the correspondingly named vertebræ.

To understand the effect of **lesions of the spinal medulla**, it is necessary to be familiar with the sensory and motor distributions of the various spinal segments (see Figs. 600, p. 720, and 610, p. 736). Transverse lesions of the spinal medulla *above the fifth cervical spine* (that is, above the fibro-cartilage between the fourth and fifth cervical vertebræ) are quickly fatal, owing to paralysis of respiration, as the phrenic nerve arises mainly from the fourth segment. In transverse lesions of the cervical enlargement the *cutaneous insensibility* does not extend higher than a transverse line at the level of the second intercostal space. The diagnosis of the particular segment involved is arrived at by testing the motor and sensory functions of each segment. The sensory areas corresponding to the *lower four cervical* and the *first two thoracic segments* occupy the upper extremities, and are placed in numerical order from the lateral to the medial side of the limb. The sensory area corresponding to the *second*, *third*, and *fourth cervical segments* occupy the occipital region of the scalp, the back of the auricle, and the masseteric region, the whole of the neck, and the shoulders and upper part of the chest down to a horizontal line at the level of the anterior end of the third intercostal space. In a total transverse lesion of the spinal medulla in the *thoracic region*, the superior limit of the anæsthesia is horizontal, and reaches to the level of the terminations of the anterior rami of the spinal nerves which arise from the spinal segment opposite the vertebral injury. Hence the superior limit of the anæsthesia is at a much inferior level than that of the injured vertebra. For example, a fracture-dislocation at the level of the eighth thoracic vertebra involves the origin of the tenth thoracic nerve which ends at the level of the umbilicus. The sensory zone corresponding to the *fifth thoracic segment* is at the level of the nipples, that of the *seventh thoracic segment* is at the level of the xiphoid process, that of the *tenth* at the level of the umbilicus, while that of the *twelfth* reaches down, anteriorly, to the superior border of the symphysis. The sensory

areas corresponding to the lumbar and sacral segments are seen in Figs. 619, p. 755, and 621, p. 763.

Goldthwait has shown that certain painful conditions, strains, and faulty postures connected with the lumbar and lumbo-sacral regions are pre-disposed to by, and associated with, architectural variations from what anatomists describe as the normal type.

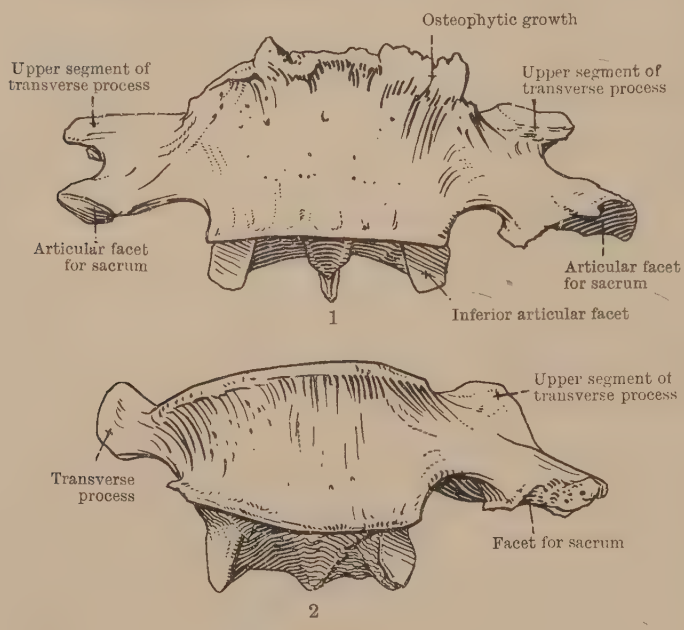

Fig. 1093.—Abnormal Fifth Lumbar Vertebræ.

In 1 both transverse processes articulated with the sacrum. In 2 only the left transverse process articulated with the sacrum.

The two well-marked variations from this normal type are (1) the congenital visceroptotic, narrow-backed, long-waisted, slender type of individual, and (2) the thick-set, broad-backed, heavy type.

In the visceroptotic type free motion takes place at the lumbo-sacral and thoraco-lumbar junctions as well as in the lumbar spine itself. The articular facets of the lumbar diarthrodial joints are less deep and less crescentic than in the normal type. The spine is, therefore, very flexible, and faulty attitudes are liable to occur. The most striking feature in this type is the exaggeration of the normal lumbar lordosis, produced principally by sharp angulation at the lumbo-sacral junction. From this region upwards the spine is comparatively straight as far as the lower cervical region, where a second sharp forward angulation takes place. This faulty attitude puts an extra strain on the sacro-iliac joint, and it is in this slender type of individual that relaxation and even displacement of the sacro-iliac joints are liable to be met with. Moreover the increased backward bending of the lumbar spine, combined with the tilting backwards of the sacrum, may result in the formation of painful bursæ or even of distinct articular facets between, more especially, the fourth and fifth lumbar and first sacral spines.

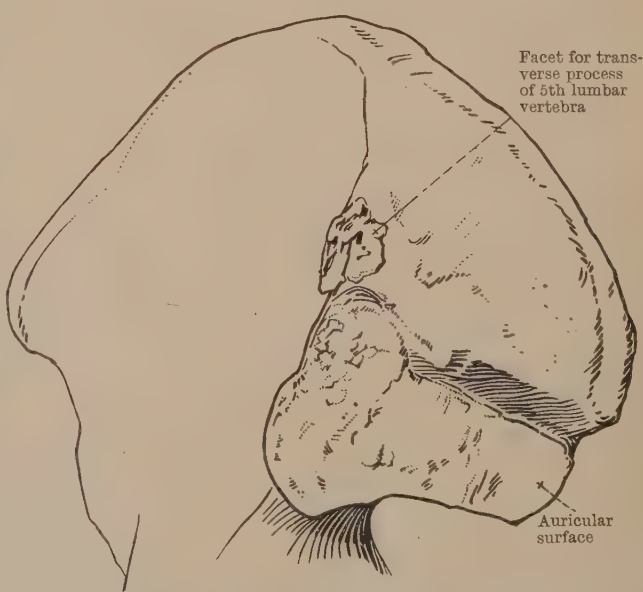

Fig. 1094.—Inner Surface of Ilium showing a Facet for the Enlarged Tip of the Fifth Lumbar Vertebra.

In the heavy, broad-backed, sthenic type of individual the lumbar vertebræ are broad and massive, the lumbar curve is comparatively slight as also is the forward inclination of the pelvis, and the axis of the sacrum approaches the perpendicular. The range of spinal movements is comparatively limited, so that a dropped and relaxed attitude of the body is anatomically more difficult to

assume. In this type the greatest strain from faulty posture is thrown upon the diarthrodial joints at the junction of the fifth lumbar vertebra with the sacrum. It is in this type, therefore, that pain and disability due to lumbo-sacral strain is most commonly met with. In these individuals flexion or forward bending of the trunk takes place mainly at the hip joint, and on account of the greater depth and crescentic shape of the lumbar diarthrodial joints lateral bending takes place more especially in the lower thoracic region, where the facets of the joints are less deep and not so crescentic. In the lumbar region lateral flexion is impossible in the extended position on account of the locking of the diarthrodial joints. When the spine is bent forwards, lateral flexion is checked also by the quadratus lumborum and intertransverse muscles. A sudden unopposed action of the quadratus lumborum has been known to tear off the tips of one or more of the transverse processes. It is the depth and crescentic formation of the articular facets in the lumbar region which are the controlling factors in limiting lateral flexion in the lumbar region. If, however, the facet on one side is shallow and flattened transversely, the whole spine is liable to become listed over to that side.

FIG. 1096.—SACRALISATION OF FIFTH LUMBAR VERTEBRA. (Compare Figs. 1093, 1095.)

The most important anatomical variations which predispose to painful conditions and abnormal postures in the lumbo-sacral region are those connected with abnormalities in the transverse processes of the fifth lumbar vertebra. Normally, these processes are short and strong and give attachment to the strong ilio-lumbar ligaments which help to sling the trunk between the innominate

bones. Sometimes these ligaments are more or less ossified on one or both sides. The comparatively short transverse processes of the fifth lumbar vertebra do not impinge against either the ilium or the sacrum during the movements of the spine. Sometimes, however, on one or the other side, this transverse process is much longer as well as much broader than normal, and when the extremity of such an elongated process, instead of being bluntly pointed, is expanded, or slightly bifid, it is liable to come in contact with the base of the sacrum, especially during lateral flexion of the spine. A bursa is always to be found between such a process and the top of the sacrum, when the former is not big enough or so situated as to form a true articulation with the sacrum, and one may form between it and the ala of the ilium (lumbo-iliac articulation). Such an articulation is, of course, developmental in origin, and by altering the statics of the spine predisposes to strain of the lower part of the back. Under such circumstances of irritation a bursitis or an arthritis of the abnormal joint not infrequently occurs. If the condition is unilateral the patient may take the pressure off the joint by listing over to the opposite side; the body of the fifth lumbar vertebra then becomes wedge-shaped, the base of the wedge being on the side of the abnormality. This is often the starting point of a scoliosis, and it may account also for the majority of cases of scoliosis associated with sciatica (scoliosis sciatica). Sometimes the transverse process of the fifth lumbar vertebra fuses not only with the base of the sacrum but also with the ilium so as to produce a complete unilateral or bilateral sacralisation of the vertebra. These "sacralisations" of the fifth lumbar vertebra, especially when unilateral and partial, are often associated with strain and osteo-arthritic changes in the lumbo-sacral and sacro-iliac joints. The presence of a lumbo-sacral transverse articulation, combined with osteo-arthritis of the sacro-lumbar joint on the same side, may result in a reduction in the size of the intervertebral foramen which transmits the anterior division of the fifth lumbar nerve. This foramen is bounded above by the lower border of the transverse process of the fifth lumbar vertebra, below by the base of the sacrum immediately medial to the psoas muscle, and laterally by the lateral lumbo-sacral ligament. Pressure on the nerve as it issues from this fibro-osseous foramen may account for the referred pain which is sometimes associated with these cases, while the branch of the fourth sacral nerve, which descends in front of the abnormal lumbo-sacral transverse articulation, is also liable to be pressed upon.

It is sometimes impossible to decide from a radiogram of the pelvis, taken in the strictly supine position, whether or not the transverse process of the fifth lumbar vertebra does actually articulate with the base of the sacrum. The difficulty is due to the circumstance that in the above position of the patient, the one usually adopted, the shadow of the posterior portion of the crest of the ilium is superimposed over the above-mentioned bones just where they would join if such an articulation existed. In order to throw the shadow of the ilium completely free of the transverse process of the fifth lumbar it is necessary to tilt the pelvis towards the opposite side; the radiographer can then say definitely whether or not this process is free from or articulates with the sacrum. Again, the manner in which the posterior part of the ilium overlaps the sacro-iliac joint makes it difficult for the radiographer to detect the presence of an osteo-arthritic or ankylosed condition of this joint. The most likely place to see these changes in a radiogram is at the lowest part of the joint shadow, where it is not overlapped by that which is cast by the posterior part of the ilium.

THE SHOULDER.

The bony landmarks of the shoulder must be systematically examined in all injuries about that region. The **medial extremity** of the **clavicle** is prominent; its articulation with the sternum forms essentially a weak joint, which is liable to be dislocated, especially from blows upon the lateral part of the shoulder which drive the medial end of the clavicle forwards against the weak anterior sterno-clavicular ligament. The **body** of the **clavicle**, subcutaneous throughout, is weakest at the junction of its two curves; it is in that region that the bone is so frequently fractured as the result of force transmitted through it to the trunk. The displacement of the lateral fragment varies according to whether the break takes place medial or lateral to the coraco-clavicular ligament; in the former case the weight of the upper extremity, acting through the coraco-clavicular ligament, pulls the lateral fragment downwards; when the fracture is lateral to the ligament, the lateral end of the clavicle rotates forwards, but there is no downward displacement. The **lateral end** of the **clavicle** is on a plane posterior to its medial end, so

that the shoulder is braced backwards away from the thorax; hence in fractures of the clavicle, both medial and lateral to the coraco-clavicular ligament, the point of the shoulder rotates forwards and medially. The **acromio-clavicular articulation** is somewhat difficult to feel; the groove which corresponds to it runs in the sagittal direction, and lies $1\frac{1}{4}$ in. medial to the lateral border of the acromion, and immediately lateral to a slight prominence upon the lateral extremity of the clavicle. When the acromio-clavicular joint is dislocated the clavicle almost invariably overrides the acromion, and the summit of the shoulder presents a somewhat conical or "sugar-loaf" appearance.

The **tip** of the **acromion** looks directly forwards, and lies a finger's breadth lateral to and a little in front of the lateral extremity of the clavicle. The **lateral border** of the **acromion** can readily be followed to its junction with the spine of the scapula, and the latter to its root, which is situated on a level with the third thoracic spine. The **medial border** of the **acromion** and the posterior border of the lateral end of the clavicle meet at an angle into which the point of the finger can be pressed. The **medial angle** of the **scapula**, covered by the trapezius and the supraspinatus muscles, is too deeply placed to be palpated distinctly. The **inferior angle**, and the **vertebral border**, from the root of the spine downwards, form visible prominences which are readily felt; the inferior angle overlies the seventh intercostal space on a level with the seventh thoracic spine, while the vertebral border lies a little medial to the angles of the ribs.

To elicit crepitus in a transverse fracture of the scapula below the spine, the surgeon stands behind the patient and grasps the upper fragment by placing the forefinger upon the coracoid and the thumb upon the spine, while, with the other hand, he grasps the inferior angle; the two fragments are then moved the one upon the other.

The **tip** of the **coracoid process** may be felt by pressing the finger firmly upon the anterior border of the deltoid at a point one inch below the junction of the middle and lateral thirds of the clavicle. Medial to the coracoid is a triangular depression which corresponds to the superior end of the interval between the clavicular fibres of the pectoralis major and deltoid muscles. Behind this triangular depression are the termination of the cephalic vein, a lymph gland, the first part of the axillary vessels, and the cords of the brachial plexus. By firm pressure in this situation the pulsation of the **axillary artery** can be felt, and by further pressure the circulation in the vessel can be arrested by compressing the artery against the second rib. The *first part* of the axillary artery may be cut down upon either by a transverse incision through the clavicular origin of the pectoralis major, or by a longitudinal incision in the interval between that muscular slip and the deltoid. The **companion vein** lies in front of, as well as to the thoracic side of, the artery, thus adding to the difficulty of exposing the vessel. In fractures of the middle third of the clavicle the subclavian vessels are protected by the soft pad formed by the subclavius muscle.

The **proximal extremity** of the **humerus**, covered by the deltoid, gives rotundity to the shoulder. The **greater tubercle** projects beyond the acromion, and constitutes the most lateral bony landmark of the shoulder. When the head of the bone is dislocated, the lateral border of the acromion then becomes the most lateral bony landmark, and the shoulder presents a square contour. The **lesser tubercle**, small but conical, can be felt through the deltoid. Pointing directly forwards, it lies one inch lateral to and a little below the level of the tip of the coracoid process. In examining the proximal extremity of the humerus for fracture, the tubercles should be grasped between the finger and thumb of one hand, while the flexed elbow is rotated with the other hand. The **head** of the **humerus** has the same direction as the medial epicondyle; its distal part can be palpated through the axilla, the arm being meanwhile abducted, to bring the head in contact with the inferior surface of the capsule. It is through this, the weakest part of the capsule, that the head is driven in the common varieties of dislocation of the shoulder, viz., those due to forcible abduction. The **proximal epiphysis** of the humerus includes the head and the greater part of the tubercles. The capsule is attached mainly to the epiphysis; hence, in children, we find that separation of the

proximal epiphysis takes the place of dislocation. Disease in the proximal end of the diaphysis does not necessarily involve the cavity of the joint. The **intertubercular sulcus** of the humerus, which lies immediately lateral to the lesser tubercle, may be mapped out upon the surface by drawing a line, two inches in length, distally along the axis of the humerus from the tip of the acromion. When there is *effusion into the joint*, the arm becomes slightly abducted, and there is fulness in front, along the line of the long tendon of the biceps. With the elbow at the side the lower part of the capsule of the shoulder-joint is loose and folded upon itself to form a dependent pocket; if, after an injury, the arm is retained too long in this position, the patient may be unable to abduct the arm, in consequence of the formation of adhesions in and around the pouch.

To evacuate pus from the shoulder-joint, the integuments, deltoid, and capsule should be cut into by an incision passing vertically and distally from the tip of the acromion.

THE UPPER EXTREMITY.

THE AXILLA.

The **anterior fold** of the **axilla**, formed by the inferior border of the pectoralis major, extends from the fifth rib to the middle of the anterior border of the deltoid. With the arm abducted, the interval between the sternal and clavicular fibres of the pectoralis major is indicated by a slight groove extending distally and laterally from the medial end of the clavicle. The sternal fibres, along with the pectoralis minor, are removed in a complete operation for malignant disease of the breast, the pectoral branches of the thoraco-acromial artery being secured as they cross the interval between the sternal and clavicular portions of the greater pectoral. The **posterior fold** of the **axilla**, formed by the latissimus dorsi and the teres major muscles, is on a lower level than the anterior fold, and leaves the chest a little in front of the inferior angle of the scapula. Between the two folds, and running in the long axis of the limb, from the axilla to the middle of the arm, is the prominence of the **coraco-brachialis muscle.** The pulsations of the **third part of the axillary artery** may be felt in the furrow, immediately behind this prominence, at the junction of the anterior and middle thirds of the lateral wall of the axilla.

Female Mamma.—The breast tissue proper is arranged to form a central portion, the *corpus mammæ*, and a peripheral portion, made up of branching processes which radiate into the paramammary fat and become continuous ultimately with the connective tissue septa of the subcutaneous fatty tissue. The mamma, therefore, has no distinct capsule. In the young adult nullipara, the corpus mammæ is compact and well defined, and contains but little intramammary fat, while the peripheral processes are relatively small. In multipara, the corpus mammæ contains more fat, and the peripheral processes extend more widely into the paramammary fat.

The arrangement and extent of the parenchyma can be well seen by treating the breast with a 5 *per cent. solution of nitric acid.* If slices of the fresh organ are placed in this solution for a few minutes and then washed under running water, the albumen of the epithelial cells of the parenchyma is coagulated, while the connective tissue is rendered translucent and somewhat gelatinous. The *ultimate lobules* of the *parenchyma* now appear as little (1 to 2 mm.), dull, opaque, white, sago-like bodies, arranged in grape-like clusters around the finer branches of the ducts.

The parenchyma is prolonged into the peripheral processes, into the suspensory ligaments of Cooper, and into the loose retromammary cellular tissue and pectoral fascia. The breast tissue, therefore, has a much wider distribution than was formerly supposed. Vertically, it extends from the second rib to the sixth costal cartilage at the angle where it begins to ascend towards the sternum; horizontally, from a little medial to the lateral border of the sternum, opposite the fourth rib, to the fifth rib in the mid-axillary line. The *medial hemisphere* of the mamma rests almost entirely on the pectoralis major; at its lowest part it slightly overlies the upper part of the aponeurosis covering the rectus abdominis muscle. The *superior quadrant* of the *lateral hemisphere* rests upon the greater pectoral, on the edge of the lesser pectoral, and to a slight extent on the serratus anterior, upon which it extends upwards into the axilla as high as the third rib, where it comes into

relation with the *thoracic* group of axillary lymph glands. The *remainder of the lateral hemisphere* rests almost entirely upon the serratus anterior, except the lowest part, which overlaps the digitations of the external oblique arising from the fifth and sixth ribs. It follows, therefore, that *fully one-third of the whole mamma lies inferior and lateral to the axillary border of the pectoralis major muscle.* The surgeon must cut beyond the above limits if he wishes to remove the whole of the mammary tissue.

The axillary fascia resists the spontaneous rupture of an axillary abscess, which, therefore, tends to spread upwards beneath the pectorals, and towards the root of the neck. To open the abscess the incision should be made upon the medial wall, behind, and parallel to, the lateral thoracic artery, which runs under cover of the anterior fold.

The **axillary lymph glands** vary greatly in size and number; many are no larger than a pin's head. In the female some of them undergo an adipose functional involution, whereby they come to resemble fat lobules. In health, one or two glands can usually be felt by thrusting the fingers upwards and medially beneath the anterior fold, the arm being only slightly abducted, so as not to stretch the axillary fascia. The *central group* (Leaf), embedded in the fat immediately beneath the axillary fascia, become inflamed in

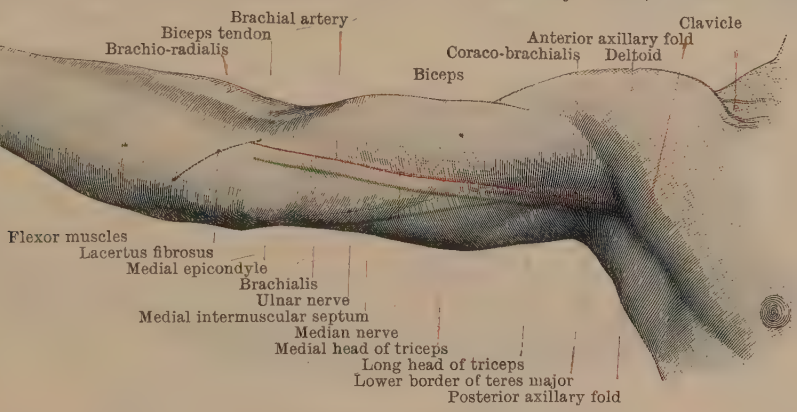

Fig. 1097.—Axilla, Medial Aspect of Arm and Elbow.

poisoned wounds of the upper extremity. The same group, along with the *pectoral group* (related to the medial wall of the axilla, at the inferior border of the pectoralis minor), are usually the first to become diseased in malignant affections of the breast. When the disease is more advanced the *posterior* (subscapular) and the *apical* (subclavicular) groups are generally affected as well; and Rotter has shown that in a considerable proportion of cases diseased glands are to be found in the *retro-pectoral fascia*, *i.e.* between the pectoralis major and minor and, above the latter muscle, on the first intercostal space in relation to the supreme thoracic artery. In operating for malignant disease of the breast, the surgeon removes, in addition to the whole breast and the greater part of the skin over it, both pectoral muscles (with the exception of the clavicular fibres of the pectoralis major), all the axillary lymph glands, and, as far as possible, all the fat and fascia, including the sheath of the axillary vein. It must be remembered that the distal part of the axillary vein lies immediately underneath the deep fascia of the lateral wall of the axilla; in cleaning the medial wall the long thoracic nerve must not be injured; and in removing the posterior group of lymph glands the thoraco-dorsal nerve, which accompanies the subscapular vessels, must be avoided, as it is doubly important to retain the action of the latissimus dorsi after removing the pectorals. The writer has so frequently met with disease in these retro-pectoral glands, that he is convinced of the necessity of removing the pectoral muscles.

THE ARM.

The anterior and posterior borders of the **deltoid** may be traced from the shoulder girdle to the insertion of that muscle. The surface relations of the anterior border have already been referred to; the posterior border forms a well-marked and important landmark as it crosses the angle between the axillary margin of the scapula and the proximal part of the body of the humerus. By making an incision along this part of the posterior border of the deltoid, and retracting the edge of the

muscle upwards and laterally, we expose the **surgical neck** of the **humerus**, and the quadrilateral opening in the posterior wall of the axilla, transmitting the posterior **circumflex artery** of the humerus and the **axillary nerve**; a little more distally is the radial nerve. The **coraco-brachialis**, the guide to the proximal half of the brachial artery, forms a prominence occupying the proximal half of the *medial bicipital furrow*. Traced distally the medial bicipital furrow widens out into an elongated triangle. This triangle, which may be termed the *medial supracondylar triangle*, becomes continuous, distally, with the medial part of the triangle in front of the bend of the elbow, and is limited posteriorly by the medial intermuscular septum, which may be felt as a cord-like band extending proximally from the medial epicondyle; the floor of the space is formed by the medial part of the brachialis. Within the triangle are the following important structures, enumerated from the lateral to the medial side, viz.: the **brachial artery**, the **median nerve**, the **distal part of the basilic vein**, the **medial cutaneous nerve of the forearm**, and the **superficial cubital lymph glands**, two or three in number. Extending proximally from the lateral epicondyle to the insertion of the deltoid is the lateral intermuscular septum, which is pierced at the junction of its proximal and middle thirds by the **radial nerve**. Between the lateral intermuscular septum and the lateral edge of the biceps is the ill-defined

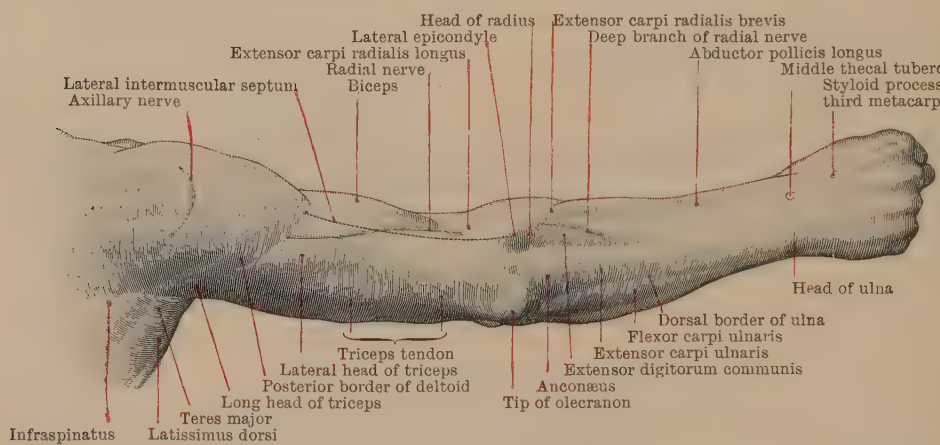

Fig. 1098.—Dorsal Aspect of Arm.

lateral bicipital furrow, the floor of which is formed by a strip of the brachialis, and, nearer the elbow, by the brachio-radialis and extensor carpi radialis longus.

The posterior compartment of the arm is occupied by the **triceps**, the *long head* of which can be traced proximally to the axillary margin of the scapula, in front of the posterior border of the deltoid and behind the posterior fold of the axilla. The *lateral head* of the triceps, after emerging from under cover of the distal part of the posterior border of the deltoid, is continued obliquely along the lateral aspect of the arm as a well-marked muscular elevation. Proximal to the olecranon is the strap-like tendon of insertion of the triceps, which, when the elbow is fully flexed, forms an admirable posterior splint in supracondylar fractures of the humerus.

The **brachial artery**, slightly overlapped in the proximal half of the arm by the coraco-brachialis and in the distal half by the biceps, can be felt pulsating throughout the whole length of the anterior part of the medial bicipital furrow. The course of the vessel may be mapped out upon the surface by drawing a line from the medial border of the coraco-brachialis, at the level of the posterior fold of the axilla, distally to a point (opposite the neck of the radius) $\frac{1}{2}$ in. distal to the middle of the bend of the elbow. In ligaturing the vessel, the edges of the coraco-brachialis and biceps muscles, together with the median nerve, furnish valuable guides to the artery, the mobility of which is often a source of trouble in performing the operation.

The **basilic vein**, which is superficial to the deep fascia in the distal third of the arm, is visible in the medial supracondylar triangle and the distal part of the

medial bicipital groove. The **cephalic vein** ascends a little anterior and medial to the lateral edge of the triceps to reach the interval between the deltoid and pectoralis major.

The surface guide for the **median nerve** is the same as that for the brachial artery. The **ulnar nerve** is indicated superficially by a line extending from the lateral wall of the axilla, immediately posterior to the prominence of the coraco-brachialis, to the back of the medial epicondyle; in the proximal half of the arm the nerve lies close behind the brachial artery under cover of the basilic vein, while in the distal half it lies a little posterior to the medial intermuscular septum, partially embedded in the fibres of the medial head of the triceps. To map out the course of the **radial nerve**, first mark the point where it pierces the lateral intermuscular septum, viz., the junction of the proximal and middle thirds of a line extending from the insertion of the deltoid to the lateral epicondyle; from that point draw a line obliquely distally and forwards to the front of the lateral epicondyle, where the nerve divides into its superficial and deep branches. To map out the nerve as it lies in the radial groove, draw a line from the same point obliquely proximally across the prominence formed by the lateral head of the triceps to the junction of the posterior fold of the axilla with the arm. In fractures of the humerus in the neighbourhood of the insertion of the deltoid, the nerve is not infrequently lacerated, or so involved in the callus as to produce the condition known as "*drop-wrist*," the result of paralysis of the extensor muscles of the forearm. To cut down upon the nerve, commence the incision a little distal to the point where it pierces the lateral intermuscular septum, and carry it obliquely proximally and slightly backwards through the lateral head of the triceps.

The **shaft** of the **humerus**, nowhere subcutaneous, is most readily manipulated in the region of the insertion of the deltoid, proximally along the lateral head of the triceps, and distally behind the lateral supracondylar ridge. The **surgical neck**, situated between the tubercles and the attachments of the muscles inserted into the region of the intertubercular sulcus, is related to the lateral wall of the axilla, and is on a level with the junction of the proximal and middle thirds of the deltoid; at the same level are the circumflex vessels and the axillary nerve.

The shaft may be cut down upon with least injury to soft parts: (1) in its *proximal third, anteriorly*, by an incision extending distally through the anterior fibres of the deltoid, parallel, and a little lateral, to the intertubercular sulcus; the sheath of the biceps will thus be avoided, and the small, anterior circumflex artery will be the only vessel divided. (2) In the *proximal third, posteriorly*, by an incision through the posterior fibres of the deltoid, the bone being reached just lateral to the origin of the lateral head of the triceps, thus avoiding the radial nerve; the circumflex vessels and the axillary nerve will be exposed at the proximal part of the wound. (3) In the *distal third*, by an incision extending upwards from the back of the lateral epicondyle a little to the medial side of the lateral intermuscular septum.

THE ELBOW.

In injuries about the elbow the diagnosis rests mainly upon the relative positions of the bony points, which are, therefore, of great importance. The **epicondyles** of the humerus are both subcutaneous and upon the same level, the medial being the more prominent. In the extended position of the elbow the tip of the **olecranon** is on a level with a line joining the epicondyles; when the forearm is flexed the olecranon descends, and when full flexion is reached it lies 1 in. distal to the epicondyles, and in a plane anterior to the posterior surface of the distal end of the humerus. The **head** of the **radius**, which lies nearly 1 in. below the lateral epicondyle, is best manipulated from behind by placing the thumb upon it, while the semi-flexed forearm is being alternately pronated and supinated. Upon the lateral part of the posterior aspect of the extended elbow is a distinct dimple, which overlies the **radio-humeral articulation**; this dimple, along with the hollows on each side of the olecranon, becomes effaced in synovial thickenings and effusions into the joint. The **coronoid process** is situated too deeply to be distinctly felt. The **distal epiphysis** of the humerus includes the

articular portion of the distal extremity and the lateral epicondyle; it is, therefore, small and almost entirely intra-articular, so that foci of disease in its neighbourhood soon invade the cavity of the joint. The medial epicondyle ossifies as a separate epiphysis which unites with the distal end of the diaphysis. In interpreting skiagrams of the elbow of children about six years of age and upwards, care must be taken not to mistake the centre of ossification in the lateral portion of the distal epiphysis of the humerus for a fracture. In the commonest dislocation of the elbow, viz., with backward displacement of both bones of the forearm, the normal relative position of the bony points is lost, whereas in a transverse supracondylar fracture the normal relations are maintained. In the child the head of the radius is relatively smaller, and less firmly kept in position by the annular ligament than in the adult, so that it is liable to be partially dislocated, giving rise to the condition known as "*pulled elbow.*"

To evacuate pus from the elbow-joint a vertical incision should be made over the dorsal aspect of the joint, immediately lateral to the olecranon.

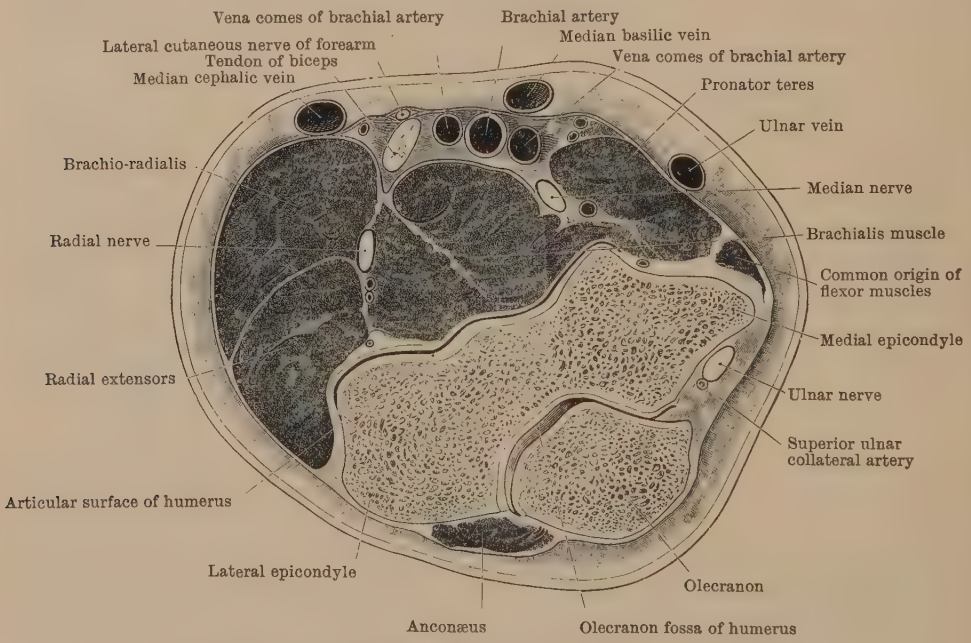

Fig. 1099.—Transverse Section through the Bend of the Elbow.

The **median vein** is seen to bifurcate into the median basilic and median cephalic veins $\frac{1}{2}$ in. distal to the middle of the bend of the elbow; opposite the same point, but beneath the deep fascia, is the **bifurcation** of the **brachial artery**. The **median basilic** and **median cephalic** veins diverge as they ascend one on each side of the biceps tendon; the larger of the two veins, viz., the median basilic, is usually selected for the operations of venesection and transfusion. When the elbow is flexed the **biceps tendon** can be traced vertically through the centre of the bend of the elbow almost to its insertion. Passing distally and medially from the medial edge of the tendon is the **lacertus fibrosus**, which separates the median basilic vein from the brachial artery. If the finger nail is insinuated beneath the medial edge of the lacertus fibrosus the point of the finger will rest upon and feel the pulsations of the brachial artery. The **median nerve** descends through the space a little medial to the brachial artery. The bifurcation of the **radial nerve** takes place in front of the lateral epicondyle under cover of the brachio-radialis. The **ulnar nerve** can be rolled beneath the finger upon the back of the medial epicondyle; its position renders it liable to injury in severe fractures about the elbow; and in excising the joint care must be taken not to injure the nerve.

THE FOREARM AND HAND.

The proximal half of the **radius** is deeply placed; the distal half, however, is easily palpated. The anterior border of its distal extremity is felt as a prominent transverse ridge, situated 1 in. proximal to the thenar eminence; immediately distal to the ridge is the **radio-carpal articulation**. The **tip** of the **styloid process**, situated nearly ½ in. more distal than that of the ulna, is deeply placed at the lateral side of the wrist, in the hollow between the extensor tendons of the first and second phalanges of the thumb. Upon the middle of the posterior surface of the distal end of the radius is the **dorsal radial tubercle**, which intervenes between the extensor pollicis longus and the short radial extensor of the wrist; the tubercle can be distinctly felt, and may be taken as a guide to the proximal end of Lister's dorso-radial incision for excision of the wrist. The dorsal border of the ulna is subcutaneous throughout, and may be felt along the interval between the flexor and extensor carpi ulnaris muscles. Upon the ulnar side of the dorsal aspect of the wrist, when the forearm is in the prone position, there is a well-marked rounded prominence formed by the **distal extremity** of the **ulna**, anterior to which is the **styloid process**, the deep groove between the two being occupied by the tendon of the extensor carpi ulnaris.

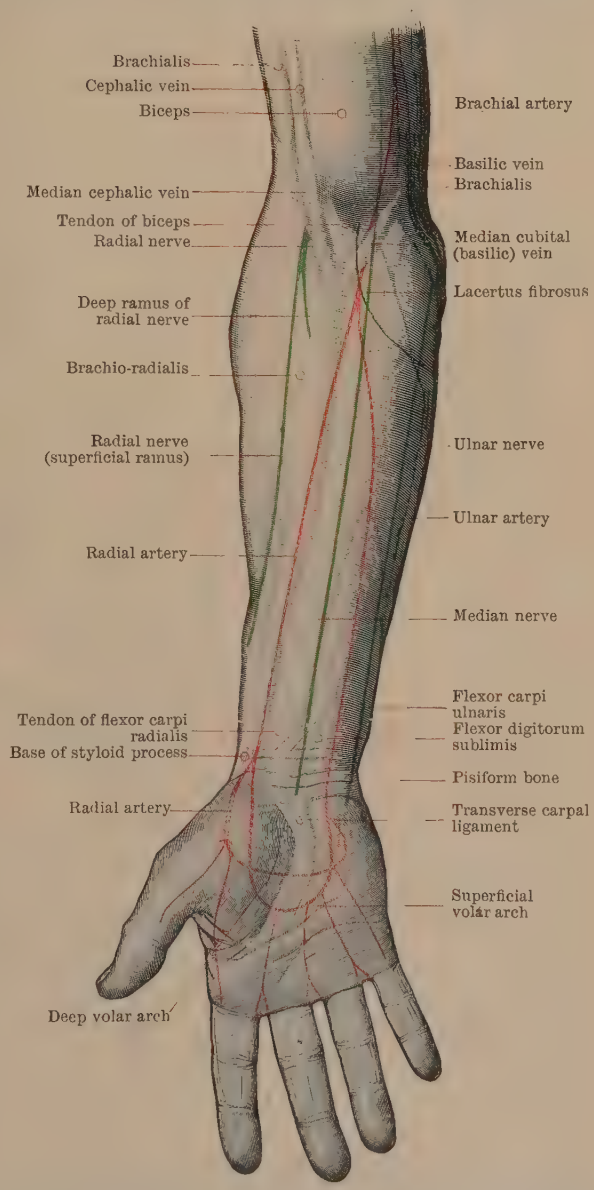

FIG. 1100.—BEND OF ELBOW, VOLAR SURFACE OF FOREARM, AND HAND.

The **carpal bones** are built up so as to form an arch, converted by the **transverse carpal ligament** into a tunnel for the transmission of the flexor tendons. At each extremity of the arch the two bony points to which the ligament is attached furnish important landmarks. These bony points are: *laterally*, the tuberosity of the navicular and the ridge of the greater multangular bone; *medially*, the pisiform and the hamulus of the os hamatum. The **tuberosity** of the **navicular** is felt immediately proximal to the root of the thenar eminence, midway between the tendons of the abductor pollicis longus and the flexor carpi radialis; ½ in. distal to the tuberosity of the navicular is the **ridge** of the **greater multangular bone**, felt deeply beneath the medial part of the thenar eminence. At the root of the hypothenar eminence,

and crossed by the crease which separates the forearm from the hand, is the **pisiform bone**, proximal to which is the tendon of the flexor carpi ulnaris, passing to be inserted into it. The **hamulus** of the **os hamatum** is felt deeply beneath the radial side of the hypothenar eminence, and a full finger's breadth distal and lateral to the pisiform.

The bases of the **first**, **third**, and **fifth metacarpals**, all of which can be readily identified on the dorsal aspect, furnish a sufficient guide to the line of the carpo-metacarpal articulations. At the base of the **third metacarpal** is a

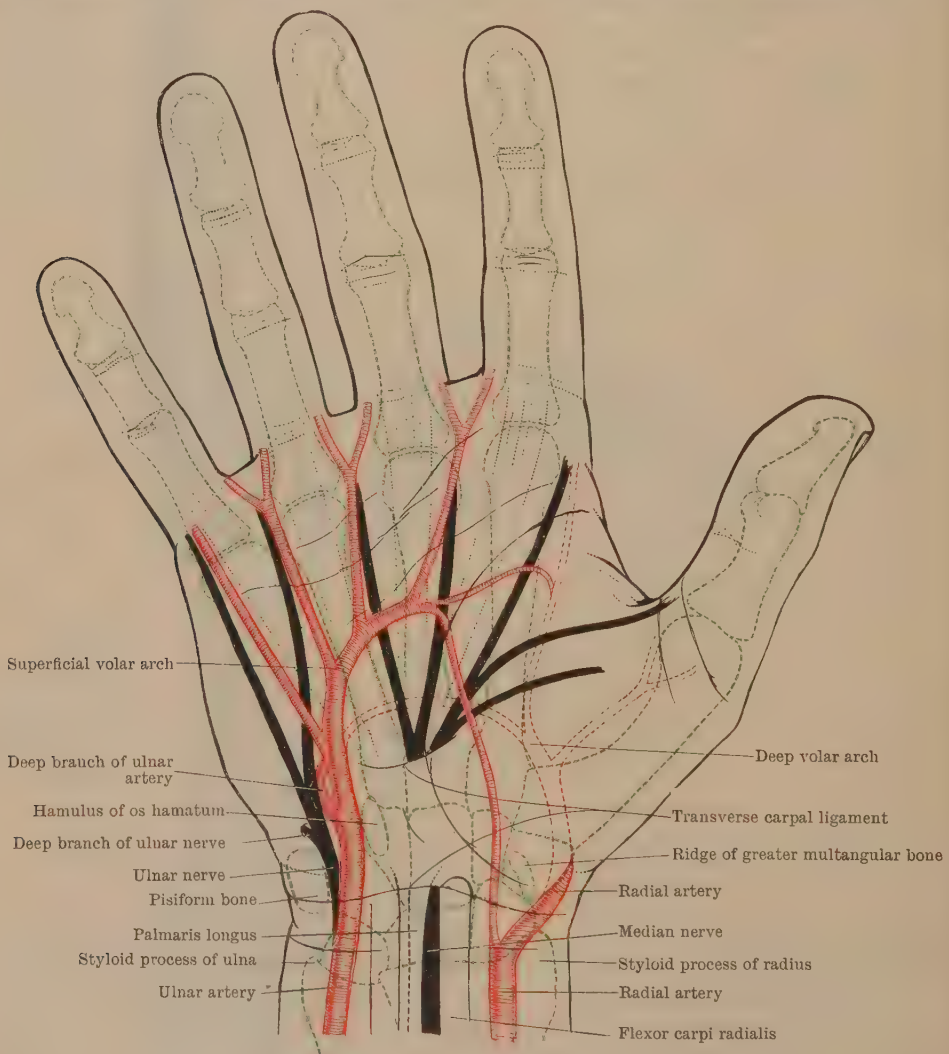

FIG. 1101.—PALM OF HAND.

tubercle, which can be felt projecting from its dorsal aspect at a point $1\frac{3}{4}$ in. vertically distal to the tubercle upon the back of the distal end of the radius. This metacarpal tubercle marks the insertion of the extensor carpi radialis brevis, the favourite site for the development of a "*ganglion*," which may frequently be ruptured by pressing it firmly against the tubercle. Anteriorly, the carpo-metacarpal articulations correspond to the distal border of the transverse carpal ligament.

The *prominences* of the *knuckles* are formed entirely by the heads of the metacarpal bones. Anteriorly, the **metacarpo-phalangeal articulations** are situated $\frac{3}{4}$ in. proximal to the level of the web of the fingers; posteriorly, the joints may be felt as a groove immediately proximal to the projecting ridge at the base of the first phalanges. A well-marked crease crosses obliquely over the anterior aspect of the

metacarpo-phalangeal joint of the thumb. To cut into the **first interphalangeal joints** from the front, incise along the *most proximal* of the creases in front of the joints; whereas to cut into the **terminal joints**, incise along the *most distal* of the creases in front of the joints. Dorsally, the first and the terminal interphalangeal articulations are opposite the most distal of the various creases overlying the joints.

The most important *muscular* landmarks upon the front of the forearm are the brachio-radialis, the flexor carpi radialis, and the pronator teres. The **brachio-**

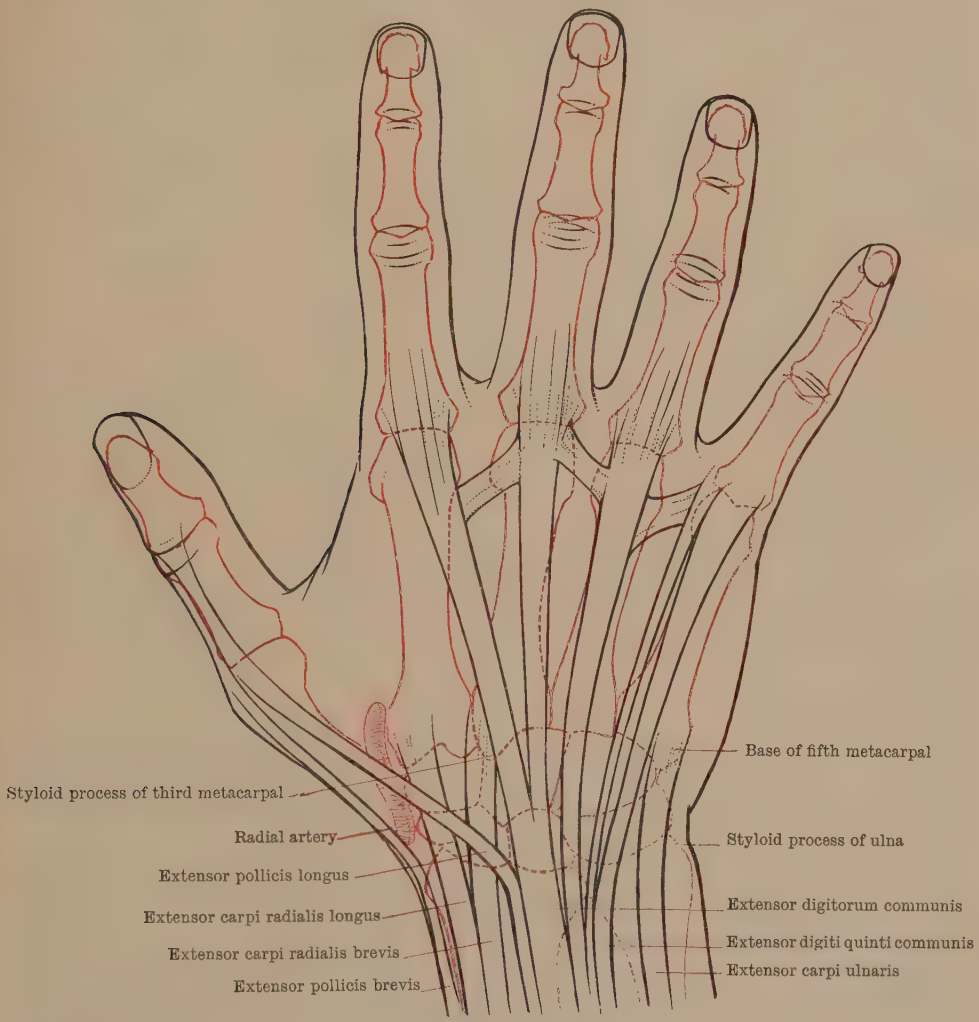

FIG. 1102.—DORSAL ASPECT OF HAND.

radialis is thrown into prominence by flexing the semi-prone forearm against resistance. At the junction of the proximal and middle thirds of the forearm the **pronator teres** passes under cover of the brachio-radialis; between the two is the radial artery. The tendon of the **flexor carpi radialis** forms a prominent landmark descending along the middle of the volar aspect of the forearm towards the ridge of the multangulum majus; the tendon of the **palmaris longus**, when present, is seen to its medial side.

At the dorsum of the forearm the intermuscular septum between the radial and common extensors corresponds to the proximal part of a line extending from the lateral epicondyle of the humerus to the tubercle on the dorsum of the distal end of the radius. The **dorsal interosseous nerve**, at the point at which it emerges from

the substance of the supinator muscle, will be found at the bottom of this septum, 2 in. distal to the head of the radius; below that point the septum is the best line along which to cut down upon the posterior surface of the radius. Winding across the distal third of the dorsal surface is an oblique prominence, caused by the abductor pollicis longus and extensor pollicis brevis muscles.

The flexor sheaths of the palm and of the digits are of surgical importance in consequence of their liability to suppurative inflammation. The **common flexor sheath** begins $1\frac{1}{2}$ in. proximal to the transverse carpal ligament, under which it extends to a little beyond the middle of the palm. The **digital flexor sheaths** extend from the bases of the terminal phalanges to the level of the distal transverse crease of the palm, opposite the necks of the metacarpal bones, *with the exception of the sheath of the little finger*, which is continuous with the common flexor sheath of the palm. The **sheath of the flexor pollicis longus** extends from the base of the terminal phalanx proximally to a point about 1 in. proximal to the transverse carpal ligament; it frequently communicates with the common flexor sheath. From this anatomical arrangement it follows that suppuration in the sheaths of the little finger and thumb is specially liable to spread upwards into the palm, and thence underneath the transverse carpal ligament into the forearm.

The pulsations of the **radial artery** can readily be felt in the distal third of the forearm, midway between the lateral border of the radius and the tendon of the flexor carpi radialis. The course of the vessel is indicated upon the surface by a line extending from the bifurcation of the brachial ($\frac{1}{2}$ in. distal to the middle of the bend of the elbow) to the tubercle of the navicular, around which, and distal to the tip of the styloid process, the artery winds to the dorsum of the radial side of the wrist; in the latter situation the vessel, after passing deep to the extensor tendons of the thumb, dips into the palm through the proximal extremity of the first interosseous space. Incisions for opening or resecting the wrist are planned so as to avoid the vessel.

The proximal third of the **ulnar artery** is deeply placed, and takes a curved course from the bifurcation of the brachial towards the medial part of the volar surface of the forearm; the distal two-thirds of the vessel correspond to the distal two-thirds of a line drawn from the front of the medial epicondyle to the radial border of the pisiform bone. The course of the **ulnar nerve** corresponds to the whole of the above line.

The **median nerve** in the forearm may be mapped out by a line extending from a point midway between the centre of the bend of the elbow and the medial epicondyle, to a point midway between the styloid processes; in the distal third of the forearm the line follows the medial border of the tendon of the flexor carpi radialis. To evacuate pus spreading deeply up the front of the forearm, the incisions should be made on either side of the line corresponding to the median nerve. The superficial branch of the **radial nerve** winds to the dorsum of the forearm round the lateral border of the radius deep to the tendon of the brachioradialis, at the junction of the middle and distal thirds of the forearm.

The summit, or most distal part of the **superficial palmar arch**, corresponds to the mid-point of a line extending from the middle of the most distal transverse crease of the wrist to the root of the middle finger; a line drawn from the radial border of the pisiform bone across the hamulus of the os hamatum, and thence in a curved direction distally and laterally to this point, corresponds to the main or proximal part of the arch; the first and fourth digital branches overlie the fifth and third metacarpal bones respectively, while the second and third overlie the fourth and third interspaces respectively. The **deep arch** lies almost transversely, midway between the distal border of the transverse carpal ligament and the superficial arch. The **radialis indicis** corresponds to the radial border of the index-finger.

The **ulnar nerve** and the commencement of its two divisions lie immediately to the medial side of the superficial palmar arch, so that the pisiform and the hamulus of the os hamatum are the guides to the nerve. The **median nerve** emerges from under the transverse carpal ligament opposite the medial edge of the thenar eminence, while the digital branches to the thumb follow its distal margin.

Incisions for the removal of foreign bodies may therefore be made into the thenar with greater freedom than into the hypo-thenar eminence.

Incisions to evacuate deep-seated pus in the palm may be made in one or more of the following situations: (1) over the distal two-thirds of the second metacarpal bone; (2) over the distal half of the fourth metacarpal bone; (3) from the proximal part of the first incision an opening may be made through the first interosseous space on to the dorsum, care being taken to keep distal to the radial artery; (4) a longitudinal incision between the median and ulnar nerves, on the proximal side of the superficial palmar arch. At the wrist a longitudinal incision may be made immediately to the ulnar side of the palmaris longus tendon, thus falling between the lines of the median nerve and the ulnar artery. To open the **digital flexor sheaths**, incisions are made along the middle of the palmar surface of the fingers, opposite the first and second phalanges. The **proper digital vessels** and **nerves** pass distally along the sides of the fingers, nearer the flexor than the extensor surfaces. In cutting down upon the dorsal aspects of the phalanges, the incisions should be made to one or other side of the extensor tendon, preferably upon the ulnar side, to avoid division of the insertions of lumbrical muscles. The subcutaneous tissue of the palmar aspect of the terminal phalanges is connected by fibrous processes with the periosteum; hence the frequency of necrosis of the terminal phalanx in suppurative inflammations in this region.

THE LOWER EXTREMITY.

THE BUTTOCK.

The region of the hip or buttock extends from the crest of the ilium above to the gluteal fold below. The highest point of the **iliac crest**, situated a little posterior to its middle, is on a level with the fourth lumbar spine; the **anterior superior spine** of the **ilium** is directed forwards, and belongs to the groin, which it limits laterally; the **posterior superior spine**, situated at the bottom of a dimple or small depression, is on a level with the second sacral spine, and corresponds, therefore, to the middle of the **sacro-iliac joint.** Two and a half inches behind the anterior superior spine is a prominence upon the outer lip of the iliac crest; this prominence, which is termed the **tubercular point**, is the most lateral part of the crest, and has been referred to in dealing with the surface anatomy of the abdomen. A hand's breadth below the tubercle of the crest is the **greater trochanter** of the femur, the most lateral bony landmark of the hip; its anterior and posterior borders are best felt between the fingers and thumb, while the limb is slightly abducted to relax the ilio-tibial tract, and if the thigh is now rotated, it will be noted that the trochanter rotates round the segment of a circle, the radius of which is formed by the head and neck of the femur; in non-impacted fractures of the neck of the femur the trochanter rotates round the segment of a much smaller circle. *Nelaton's line*, drawn from the anterior superior spine to the most prominent part of the ischial tuberosity, crosses the hip at the level of the proximal border of the greater trochanter; this line is employed to ascertain the presence or absence of upward displacement of the trochanter. Chiene demonstrates the relative height of the trochanters by stretching two tapes across the front of the pelvis, one between the anterior superior spines, and the other between the proximal borders of the trochanters; the lower tape will converge towards the upper on the side of the upward displacement. A line prolonging the anterior border of the greater trochanter vertically upwards touches the iliac crest at the tubercular point. The **sciatic tuberosity**, in the erect posture, is overlapped by the distal border of the glutæus maximus; its most prominent part is felt a little proximal to the medial part of the gluteal fold. If the hip is rotated medially, the **lesser trochanter** of the femur may be felt by deep palpation proximal to the lateral end of the gluteal fold; it corresponds to the interval between the distal border of the quadratus femoris and the proximal border of the adductor magnus, and therefore, also, to the level of the medial circumflex artery of the thigh.

The **lower border** of the **glutæus maximus** lies a little above the **gluteal fold**

medially, crosses it about its middle, and is continued distally and laterally to meet the proximal end of the furrow of the lateral intermuscular septum, at the junction of the proximal and middle thirds of the femur. The medial borders of the two great gluteal muscles are separated by the deep **gluteal cleft**, which extends upwards and backwards from the perineum to the level of the fourth sacral spine, where it opens out into the triangle upon the back of the sacrum. Anteriorly the buttock is limited by the prominence of the **tensor fasciæ latæ muscle**, which extends distally and somewhat backwards from the anterior end of the crest, to join the ilio-tibial tract distal to the root of the greater trochanter.

The superior **gluteal artery** reaches the buttock immediately below the upper border of the greater sciatic foramen, opposite a point corresponding to the junction of the upper and middle thirds of a line drawn from the posterior superior iliac spine to the upper border of the greater trochanter. To expose the vessel the

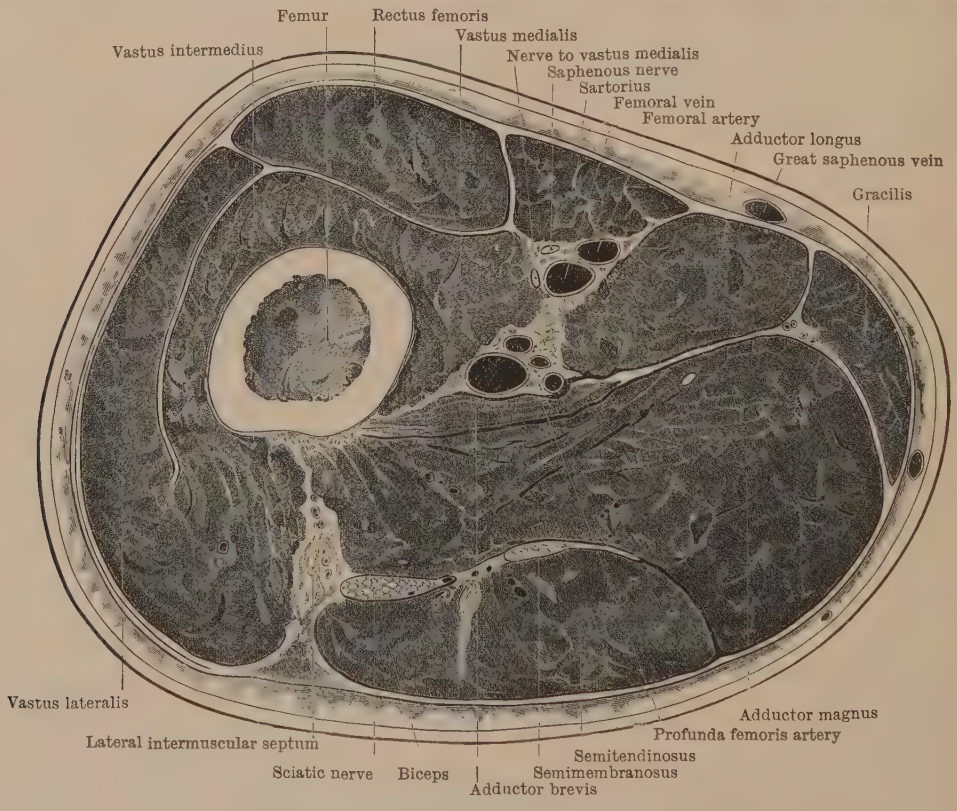

Fig. 1103.—Section through Thigh at the Level of the proximal part of the Adductor Canal.

incision should be made along this line, which has the advantage of running parallel to the fibres of the glutæus maximus, as well as parallel to the interval between the glutæus medius and piriformis muscles.

The **sciatic nerve** enters the buttock at a point corresponding to the junction of the upper and middle thirds of a line drawn from the superior posterior iliac spine to the sciatic tuberosity; from this point the nerve passes downwards and slightly laterally upon the ischium to a point midway between its sciatic tuberosity and the greater trochanter. The **spine of the ischium** and the **pudendal vessels** are situated opposite the junction of the lower and middle thirds of the above line. The vessels and nerves which enter the buttock through the greater sciatic foramen *below the piriformis* may be exposed through an incision below and parallel to that above described for exposing the superior gluteal artery, viz., an incision corresponding to the middle two-fourths of a line extending from the upper end of the gluteal cleft to the root of the greater trochanter; the deep landmarks are the lower border of the piriformis and the root of the sciatic spine.

THE BACK OF THE THIGH.

The **hamstring muscles**, and especially the tendon of the biceps and semitendinosus, are thrown into prominence either by standing on tiptoes with the knees slightly flexed, or by flexing the leg against resistance. By throwing the hamstrings into action, the line of the **lateral intermuscular septum** of the thigh is indicated by a well-marked furrow, extending from the lower edge of the insertion of the glutæus maximus to the lateral aspect of the knee; behind this furrow is the **biceps femoris**, and in front of it is the large **vastus lateralis**, covered by the strong ilio-tibial tract of the fascia lata. The **shaft of the femur** may be cut down upon along the whole length of this furrow with least injury to the soft parts; the popliteal surface of the femur and deep-seated popliteal abscesses are most conveniently reached through the lower part of the same incision.

The course of the **sciatic nerve** corresponds to the proximal half of a line

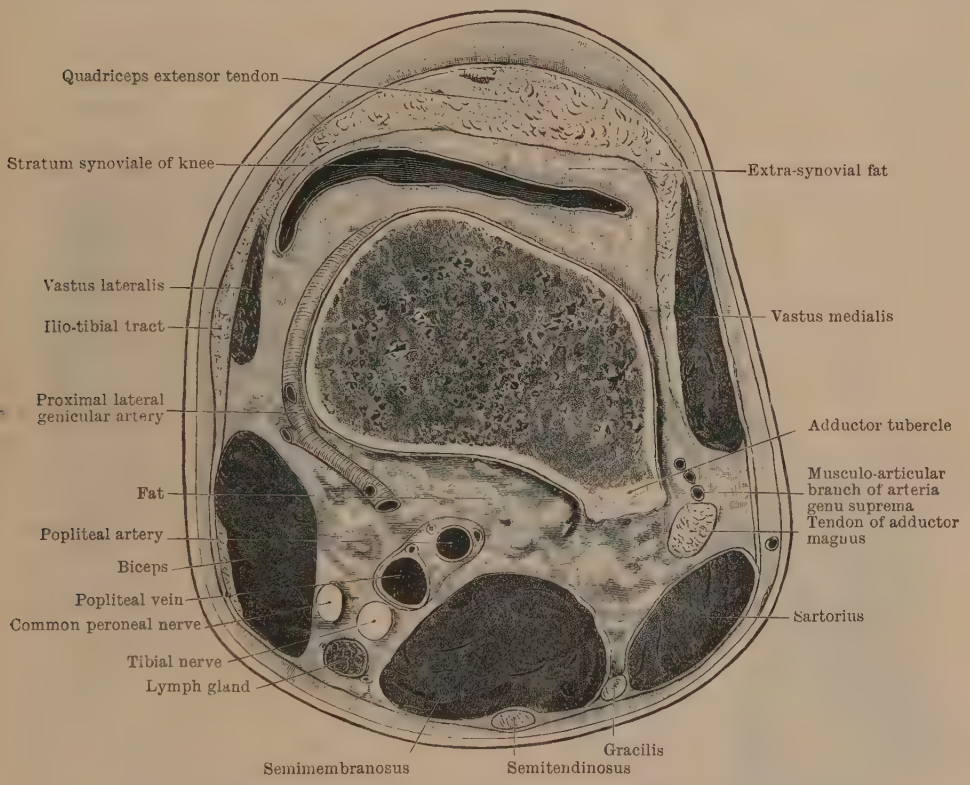

FIG. 1104.—SECTION THROUGH THE THIGH IMMEDIATELY PROXIMAL TO THE PATELLA.

extending from a point midway between the sciatic tuberosity and the greater trochanter to the centre of the popliteal fossa. The nerve enters the thigh under cover of the lateral border of the biceps, whereas the **posterior cutaneous** nerve of the thigh which takes the same line, descends superficial to the biceps, between it and the fascia lata. In the operation of stretching the sciatic nerve it is cut down upon immediately distal to the lower border of the glutæus maximus. The surgeon, standing on the side of the patient opposite to the leg to be operated upon (Chiene), makes an incision in the line of the nerve through the integuments and fascia lata, and, sweeping the index-finger round the lateral border of the biceps, hooks up the nerve as it lies between that muscle and the adductor magnus.

The **common peroneal nerve** may be rolled under the finger as it passes distally immediately behind the tendon of the biceps and the head of the fibula; so close is

the nerve to the tendon that the tendon should be divided, in cases where this is necessary, by the open method rather than subcutaneously.

Abscesses may reach the flexor compartment of the thigh from various sources, viz. : (1) from the posterior aspect of the hip-joint; (2) from the pelvis, through the greater sciatic foramen; (3) from one or other of the bursæ under the glutæus maximus; (4) from the front of the hip-joint, by passing backwards under the tensor fasciæ latæ; or by winding backwards beneath the neck of the femur, and through the interval between the quadratus femoris and the adductor magnus; (5) from the iliac fossa under the inguinal ligament into the fascial trigone, and thence to the back of the thigh by one or other of the routes already mentioned; (6) the pus may spread proximally from the popliteal surface of the femur, the knee, a popliteal gland, or from a bursa.

THE POPLITEAL FOSSA.

When the knee is extended the **popliteal fascia** is put upon the stretch, and obliterates the hollow of the popliteal fossa; by flexing the knee the fascia is relaxed, and the fingers may be pressed deeply into the proximal or femoral

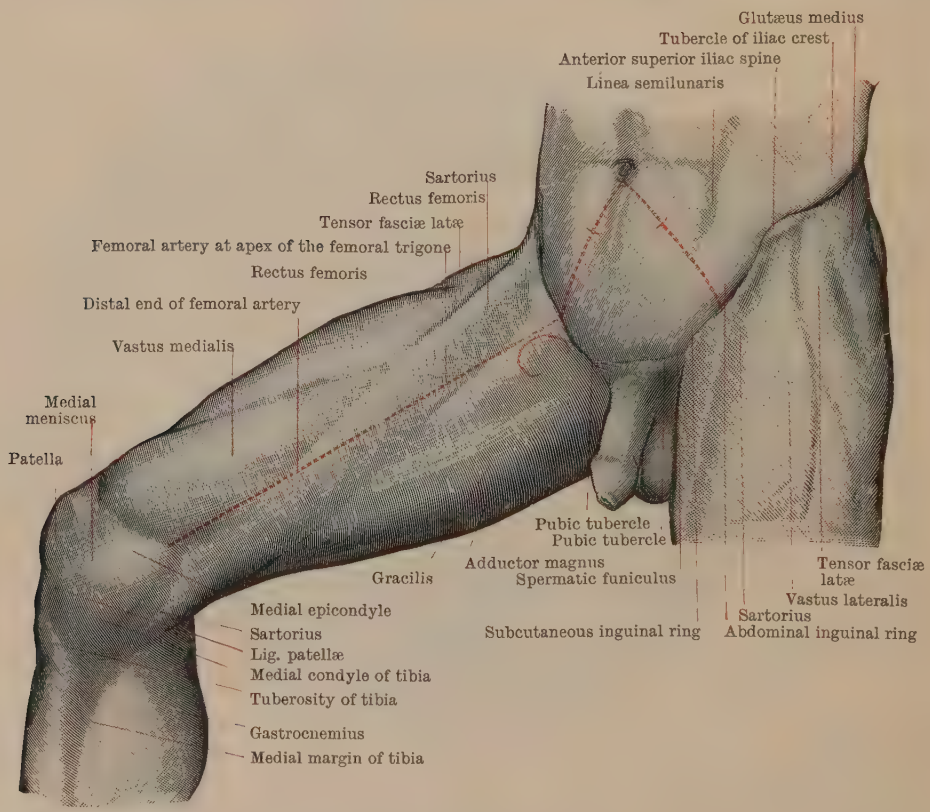

FIG. 1105.—THE THIGH AND GROIN.

division of the fossa; as a rule, the pulsations of the popliteal artery can be felt. Deep to the **semitendinosus** is the fleshy **semimembranosus**, which bulges into the space and overlaps the proximal part of the popliteal artery. Between the semimembranosus and the medial head of the gastrocnemius is the most important **bursa** in the popliteal region; it not infrequently becomes distended with fluid, and then presents usually a more or less sausage-shaped outline; according to Holden, the bursa communicates with the cavity of the knee-joint in one subject out of five.

To map out the line of the **popliteal vessels** and the **tibial nerve**, draw a line from a point a little medial to the proximal angle of the space to a point midway between the condyles of the femur, and thence distally along the middle of the space to the level of the distal part of the tuberosity of the tibia. The tibial nerve

lies immediately under cover of the deep fascia; the artery is separated from the popliteal surface of the femur by a quantity of fat. The popliteal **lymph glands** lie deep to the popliteal fascia, one upon the tibial nerve, the others deeply in the space (Leaf).

THE FRONT OF THE THIGH.

Between the front of the thigh and the abdomen is the *fold of the groin*, at the bottom of which the **inguinal ligament** can be felt as a tense band, stretching from the anterior superior spine of the ilium to the pubic tubercle. The **anterior superior spine** looks directly forwards; comparative measurements of the inferior extremities are made by stretching a tape from it to the tip of one or other of the malleoli, care being taken that the pelvis is horizontal, and the limbs in corresponding positions. The **pubic tubercle** is felt under the proximal and lateral part of the mons Veneris and at a corresponding point in the male; between the tubercle and the symphysis is the **crest** of the pubis, the two crests together forming a rounded subcutaneous bony ridge. A line extending from the pubic tubercle horizontally laterally across the front of the thigh crosses the front of the hip-joint at the level of the inferior part of the head of the femur. The cord-like **tendon** of the **adductor longus** is readily felt, and a point about 1 in. below the pubic tubercle is selected for performing the operation of subcutaneous tenotomy of the tendon.

The centre of the **fossa ovalis** is situated $1\frac{1}{2}$ in. distal and lateral to the pubic tubercle; it overlies the medial (hernial) and intermediate (venous) compartments of the femoral sheath; behind the lateral border of the opening is the arterial compartment of the sheath; crossing over the distal border is the termination of the great saphenous vein. A femoral hernia makes its way into the thigh below the proximal edge of the opening. The course of the **great saphenous vein** in the thigh is indicated by a line extending from the adductor tubercle of the medial epicondyle of the femur to the distal part of the fossa ovalis.

The **horizontal** or **subinguinal chain** of **lymph glands** can usually be felt along, and a little distal to, the line of the inguinal ligament; when the glands are inflamed the surgeon should not neglect to examine the buttocks and anus as well as the external genitals. The **vertical** or **femoral chain** lies in close relation to the upper end of the great saphenous vein. Deeper glands also are met with deep to the fascia cribrosa, close to the medial side of the femoral vein, and there is generally one in the femoral canal. To clear out the glands in the groin an incision should be made parallel to, and a finger's breadth distal to the whole length of the inguinal ligament.

To map out the course of the **femoral artery**, the thigh being slightly flexed and rotated laterally, draw a line from the mid-point between the anterior superior iliac spine and the symphysis pubis to the adductor tubercle at the proximal and posterior part of the medial epicondyle; rather less than the proximal third of this line corresponds to the femoral artery in the femoral trigone, while rather more than its middle third corresponds to the artery as it lies in the adductor canal. The seat of election for ligature of the vessel is at the apex of the femoral trigone. To compress the femoral, pressure should be made directly backwards against the ilio-pectineal eminence, and not against the head of the femur; to compress the femoral in the adductor canal, pressure should be made laterally against the medial surface of the shaft of the femur.

On the lateral aspect of the thigh the **fascia lata** is thick, aponeurotic, and loosely attached to the vastus lateralis; hence the tendency of abscesses to travel distally under cover of it towards the knee. The **sartorius**, which forms the most important muscular landmark of the thigh, may be thrown into prominence by maintaining the thigh unsupported, flexed, and slightly rotated laterally. Observe that in the proximal third of the thigh it forms the lateral boundary of the femoral trigone; in the middle third it is placed superficial to the adductor canal; while in the distal third it lies in front of the medial hamstrings. Lateral and adjacent to the proximal part of the sartorius is the prominence of the **tensor fasciæ latæ**, which, as it passes to its insertion, diverges from the sartorius; in the angle

between the two the tendon of the rectus femoris may be felt as it overlies the distal part of the anterior aspect of the articular capsule of the hip.

The medial aspect of the distal half of the **shaft of the femur** may be conveniently cut down upon through the vastus medialis, where it comes to the surface between the sartorius and rectus muscles; the incision should be made in the direction of a line extending from a point midway between the medial border of the patella and the adductor tubercle, to the anterior superior iliac spine.

The front of the **hip-joint** may be reached through an incision from the anterior superior iliac spine distally, along either the medial or the lateral border of the sartorius; in the former case the deeper part of the dissection passes between the iliacus and the medial border of the rectus femoris, while in the latter case the joint is reached lateral to the rectus tendon, between it and the anterior borders of the glutæus medius and minimus muscles. The ascending branch of the **lateral circumflex artery** of the thigh crosses the capsule parallel to, and immediately above, the inter-trochanteric line. The **ilio-psoas** crosses the anterior and the medial part of the capsule; between the two is a **bursa**, which frequently communicates with the joint through the thin part of the capsule medial to the ilio-femoral ligament; it is by way of this communication that a psoas abscess occasionally gives rise to secondary tubercular disease of the hip-joint. One of the commonest situations to meet with an abscess in hip-joint disease is in the cellular tissue and fat under the tensor fasciæ latæ; or the pus may pass below and to the medial side of the neck of the femur, and thence along the course of the medial circumflex artery of the thigh to the back of the thigh. *To tap or explore the hip-joint*, the puncture should be made in the interval between the sartorius and the tensor fasciæ latæ, 2 to 3 in. distal to the anterior superior iliac spine; if the instrument is then pushed upwards, medially and posteriorly beneath the tendon of the rectus femoris, it will pass through the capsule a little above the inter-trochanteric line. Regarded from the point of view of **dislocation**, the regions of the acetabular notch and of the inferior part of the capsule are the weak points in the joint; it follows, therefore, that abduction favours dislocation by bringing the head of the femur into relation with these two weak areas.

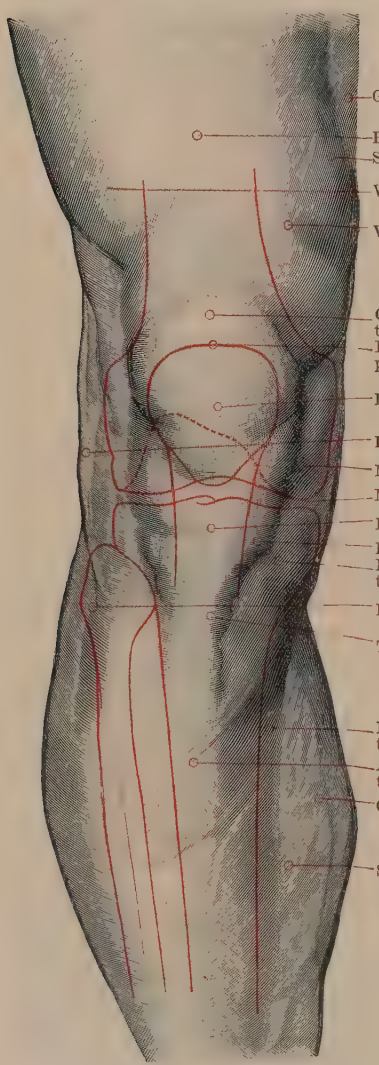

FIG. 1106.—ANTERIOR ASPECT OF KNEE.

THE KNEE.

With the knee extended and the quadriceps relaxed, the **patella** can be readily outlined and moved from side to side upon the femoral condyles. When the quadriceps is contracted its tendon springs forwards and is felt as a tense band above the patella; while the **lig. patellæ**, which has become tense and prominent, may be traced to the distal part of the tuberosity of the tibia. In front of the distal part of the patella and of the proximal part of the lig. patellæ is the **pre-patellar bursa**, into which effusion takes place in the condition known as housemaid's knee. Deep to and on each side of the ligamentum patellæ is a well-circumscribed pad of fat, palpation of which gives rise to a feeling closely resembling true fluctuation. In extension, only the distal pair of articular facets of the patella are in contact with the trochlear surface of the femur. In semi-

flexion the middle pair of facets rests upon the trochlea; in this position the medial margin of the medial condyle, the proximal border of the medial condyle of the tibia, and the distal part of the patella are all distinctly visible, and together bound a triangular depression, which overlies the line of the joint and contains the anterior part of the **medial meniscus**; it is in this triangle that the surgeon searches for a displaced or thickened medial meniscus, for a loose body, and for "lipping" of the edge of the articular cartilage in chronic osteo-arthritis. A similar, but less well-defined, triangle may be felt immediately lateral to the distal edge of the patella. When the quadriceps is thrown into sudden or violent contraction, as in preventing oneself from falling backwards, the patella may be transversely fractured at the moment of partial flexion. In full flexion almost the whole of the trochlear surface of the condyles is exposed to palpation, covered, however, by the stretched quadriceps tendon.

The proximal part of the medial surface of the medial condyle is overlapped by the muscular prominence of the distal fibres of the **vastus medialis**. Leading proximally from the medial condyle is a slight furrow, corresponding to the interval between the distal part of the vastus medialis and the sartorius; at the bottom of the furrow the cord-like **tendon of the adductor magnus** may readily be felt, and followed to its insertion into the **adductor tubercle**; the latter, situated at the junction of the medial supra-condylar ridge with the proximal and posterior part of the medial condyle, marks the level of the **epiphyseal cartilage**. Anteriorly and posteriorly the epiphyseal cartilage lies just proximal to the highest part of the articular cartilage.

Disease of the distal end of the body of the femur generally invades the popliteal surface of the femur and the popliteal fossa rather than the cavity of the knee-joint. In *Macewen's operation for knock-knee*, the incision (through which the osteotome is introduced to divide the femur) is carried down to the bone through the vastus medialis a little proximal to the medial condyle, a finger's breadth proximal to the summit of the trochlea, to avoid injury to the epiphyseal cartilage, and the same distance in front of the adductor tendon, to avoid injury to the musculo-articular branch of the arteria genu suprema.

Distal to the medial condyle is the subcutaneous **medial condyle of the tibia**, across which the tendons of the sartorius, gracilis, and semitendinosus pass to their insertions. Between those tendons and the medial head of the gastrocnemius is a groove which winds distally and forwards from the popliteal space; an incision along this groove will expose the **great saphenous vein** and **saphenous nerve** and the superficial or saphenous branch of the arteria genu suprema.

On the lateral side of the knee is the **ilio-tibial tract**, which, after crossing and obscuring the line of the joint, is attached to the **lateral condyle of the tibia**. By semiflexion of the knee the posterior border of the tract is thrown into relief, and a well-marked furrow intervenes between it and the prominent tendon of the biceps; the distal part of the shaft of the femur and the popliteal surface may be reached through an incision along this furrow. Under cover of the ilio-tibial tract, as it crosses the line of the joint, are the **lateral meniscus**, the **distal lateral genicular artery**, and the **fibular collateral ligament**. The **head of the fibula**, and the **tendon of the biceps** passing to be inserted into it, are rendered distinctly visible by semiflexing the knee; the former lies on a level with the tuberosity of the tibia, $1\frac{1}{2}$ in. posterior and a little distal to the most prominent part of the lateral condyle of the tibia. Immediately distal to the head of the fibula is the termination of the **common peroneal nerve**, which is liable to be contused from blows, and in fractures of the neck of the fibula.

The **synovial layer** of the knee-joint extends distally, anteriorly, as far as the level of the proximal border of the tibia; posteriorly, it dips distally for a short distance behind the popliteal notch of the tibia, to form a small cul-de-sac, the close relation of which to the popliteal artery must be borne in mind in performing the operation of excision of the knee. Anteriorly, the synovial layer extends proximally beneath the quadriceps in the form of a pouch, which reaches nearly two inches proximal to the articular surface of the femur; posteriorly, there is no extension of the synovial cavity proximal to the condyles; at the sides of the knee the synovial layer covers the anterior third of the superficial surface of each condyle.

In **effusion into the knee-joint** the hollows become obliterated, the patella is floated up, and fluctuation may be obtained proximal, distal, and to either side of the patella.

To pass a tube through the knee-joint for drainage, two short vertical incisions should be made—one on each side of the joint at the level of the proximal part of the patella, and a finger's breadth behind its lateral edges. In **arthrectomy** of the knee for tubercular disease, the subsynovial fat facilitates the separation of the supra-patellar pouch from the distal and anterior part of the shaft of the femur; to expose the **pouches posterior to the condyles**, the cruciate ligaments must be divided.

THE LEG.

The medial surface of the **tibia** is subcutaneous throughout; hence the seat of a fracture of the shaft is, as a rule, easily felt, and the distal extremity of the proximal fragment is liable to perforate the skin. The skin over the distal half of this surface is the commonest seat of varicose and callous ulcers, which are frequently prevented from healing by adhesion of the floor of the ulcer to the periosteum.

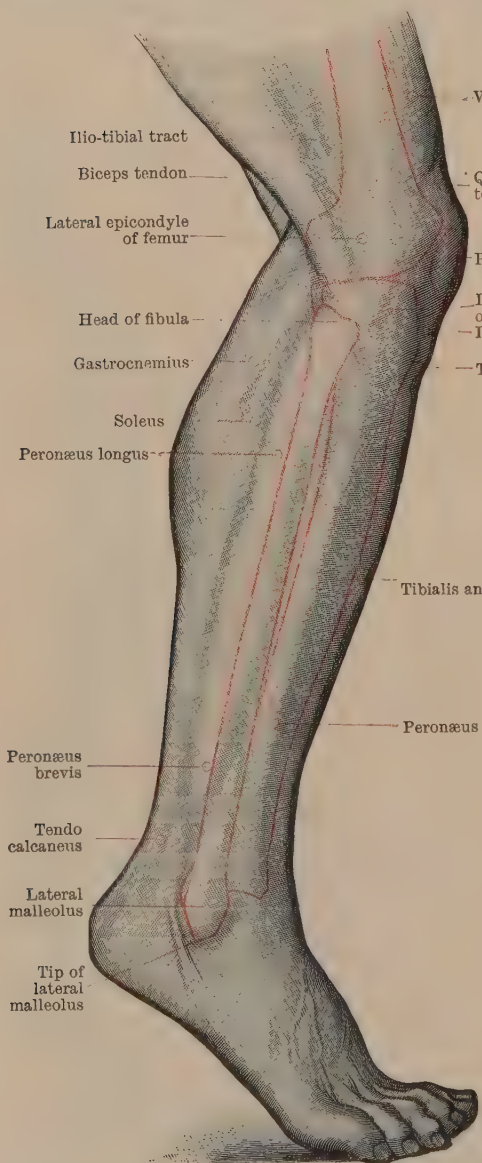

FIG. 1107.—LATERAL ASPECT OF KNEE AND LEG.

The **shaft of the fibula**, situated on a plane posterior to that of the tibia, is, with the exception of the triangular subcutaneous surface proximal to the lateral malleolus, deeply placed amongst the muscles. To examine the fibula, the surgeon should stand on the opposite side of the patient and manipulate the bone along the line of the intermuscular septum between the peronæi and the muscles of the calf.

The greater fulness of the antero-lateral surface of the leg, as compared with its medial surface, is due to the presence of the **extensor** and **peroneal groups of muscles**. When those groups are thrown into action, the individual muscles are mapped out upon the surface by the grooves corresponding to their intermuscular septa. The **posterior peroneal septum** is seen as a well-marked furrow, extending from the posterior aspect of the head of the fibula to the hollow behind the lateral malleolus; in front of it are the **peronæi muscles**, the *longus* giving rise to a prominence on the proximal half of the leg, while the *brevis* is prominent on the distal half; behind the septum is a prominence formed by the lateral border of the **soleus**, which projects beyond the border of the **gastrocnemius**.

It is along the line of the posterior peroneal intermuscular septum that incisions should be made to expose the fibula; to avoid the superficial peroneal nerve, however, the incision must not extend to a more proximal level than one inch distal to the head of the fibula.

The furrow between the extensors and the two peronæi, the **anterior peroneal septum**, is much less distinct, and runs in a line from the anterior border of the head of the fibula to the anterior border of the lateral malleolus; the **cutaneous portion of the superficial peroneal nerve** corresponds to the distal half of this line. At the junction of the middle and distal thirds of the leg the extensor muscles incline medially over the anterior aspect of the tibia.

The **anterior tibial artery** reaches the front of the interosseous membrane 2 in. distal to the tuberosity of the tibia; in the proximal two-thirds of its course it lies upon the interosseous membrane, while in its distal third it winds on to the front of the tibia, to terminate at a point opposite the ankle-joint, midway between the two malleoli. *Incisions to expose the vessel* should strike the lateral border of the tibialis anterior, which corresponds to a line drawn from a point midway between the lateral condyle of the tibia and the head of the fibula, to the termination of the vessel.

When the muscles of the calf are thrown into action, a groove is seen between the two heads of the **gastrocnemius**, the fleshy fibres of which extend a little distal to the middle of the leg. The fleshy fibres of the **soleus** extend to the junction of the middle and distal thirds of the leg, and project beyond the margins of the gastrocnemius. The narrowest part of the **tendo calcaneus** is situated opposite the bases of the malleoli, and it is there that the tendon is divided in the operation of tenotomy. The **small saphenous vein**, which lies a little to the lateral side of the tendon, gradually reaches the middle of the calf, along which it runs proximally to the middle of the popliteal fossa. The **great saphenous vein** and the **saphenous nerve** lie along the medial margin of the tibia.

The course of the **posterior tibial artery** is mapped out by drawing a line from the distal angle of the popliteal fossa, at the level of the distal border of the tuberosity of the tibia, to a point midway between the medial malleolus and the tendo calcaneus. *To expose the vessel* in the proximal half of the leg, an incision is made parallel to and $\frac{1}{2}$ in. posterior to the medial margin of the tibia; after retracting the medial border of the gastrocnemius and dividing the tibial origin of the soleus, the artery is found lying on the tibialis posterior. In exposing the artery below the soleus, divide two layers of deep fascia and keep the knife directed towards the tibia.

The **peroneal artery** is given off 3 in. distal to the head of the fibula; incisions to expose the vessel are made in the direction of a line extending from the posterior border of the head of the fibula to a point midway between the lateral malleolus and the tendo calcaneus.

THE FOOT AND ANKLE.

The tip of the **lateral malleolus** is situated $\frac{1}{4}$ in. distal and $\frac{3}{4}$ in. more posterior than that of the **medial malleolus**. Proximal to the lateral malleolus is the triangular subcutaneous surface of the fibula, the apex of which corresponds to the distal end of the extensor-peroneal intermuscular septum.

The **line of the ankle-joint** can be felt on either side of the extensor tendons, and when the foot is extended the anterior part of the proximal articular surface of the **talus** forms a visible prominence distal to the anterior crest of the distal end of the tibia. The small posterior surface of the talus is felt distal and posterior to the medial malleolus, at the anterior part of the hollow between it and the heel. In *effusions into the ankle-joint* the hollows in front and behind the malleoli are obliterated, and the extensor tendons are raised from the front of the joint.

A finger's breadth distal to the tip of the medial malleolus is the **sustentaculum tali**; $1\frac{1}{4}$ in. in front of the sustentaculum, and midway between the dorsal and plantar margins of the medial aspect of the foot, is the **tuberosity of the navicular** (the medial landmark in Chopart's amputation), which is generally visible, and

always distinctly palpable. The **calcaneo-taloid joint** lies immediately above the sustentaculum, while close above it the **tendon of the tibialis posterior** may be rendered visible, as it extends from behind the tip of the medial malleolus to the tuberosity of the navicular. An inch and a half in front of the tuberosity of the navicular is the **joint between the first cuneiform and the first metatarsal**; the ridge at the base of the first metatarsal furnishes a good guide to the articula-

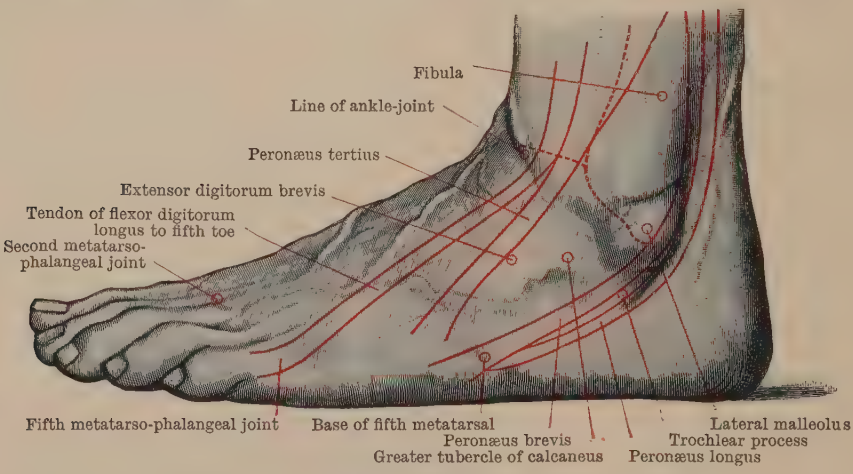

FIG. 1108.—LATERAL ASPECT OF FOOT AND ANKLE.

tion. The first **metatarso-phalangeal joint** lies a little in front of the middle of the ball of the great toe.

A finger's breadth vertically below the tip of the lateral malleolus is the **trochlear process** of the calcaneus, and midway between the two is the **calcaneo-taloid joint**; the trochlear process is, when present, a trustworthy guide to the level at which the **two peronæi tendons** cross the lateral surface of the calcaneus. The **greater process** of the **calcaneus** is felt in the triangular interval between the tendons of the peronæus brevis and tertius; the **calcaneo-cuboid joint**—the lateral

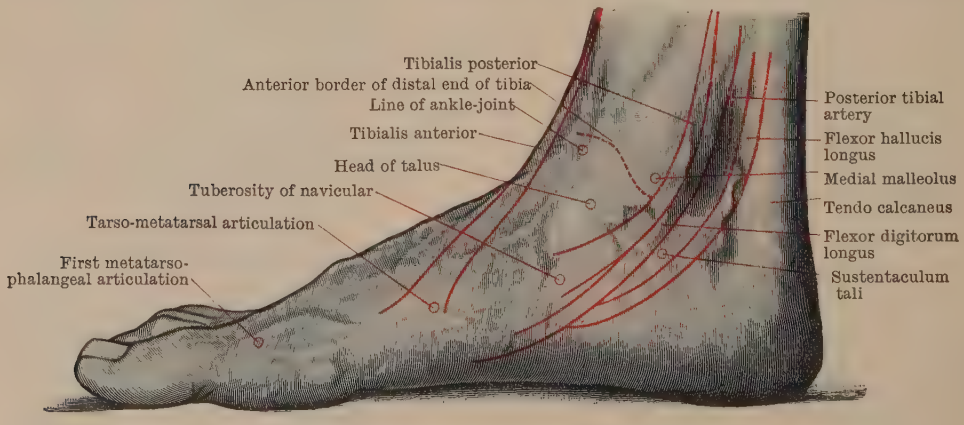

FIG. 1109.—MEDIAL ASPECT OF FOOT AND ANKLE.

landmark in Chopart's amputation—is placed a little in front of the mid-point between the tip of the lateral malleolus and the base of the fifth metatarsal bone. To open the **lateral tarso-metatarsal articulations**, the knife, entered behind the projecting base of the fifth metatarsal bone, should be directed forwards as well as medially. On the dorsum of the foot the tarsal joints are obscured by the extensor tendons. The **synovial layer** of the **ankle-joint** is prolonged on to the neck of the talus, and care must be taken to avoid opening the ankle-joint in performing Chopart's amputation.

The **line** of the **tarso-metatarsal joints** extends nearly 1 in. further forwards on the medial than on the lateral border of the foot; between these points the joint-line takes a zigzag course on account of the second metatarsal bone extending backwards between the first and third cuneiform bones. The joint between the second metatarsal and second cuneiform is nearly $\frac{1}{2}$ in. behind that between the first metatarsal and first cuneiform, and nearly $\frac{1}{4}$ in. behind that between the third metatarsal and the third cuneiform. The strong transverse interosseous ligament (*Lisfranc's ligament*), which connects the lateral surface of the first cuneiform with the base of the second metatarsal, must be divided in the tarso-metatarsal amputation of Lisfranc. In order to preserve the insertions of the two tibial and the three peroneal muscles, it is advisable, when possible, instead of disarticulating at "Lisfranc's joint," to saw through the metatarsal bones just in front of their bases.

The **metatarso-phalangeal articulations** are situated 1 in. behind the web of the toes. In disarticulating a toe, the transverse metatarsal ligament, which unites the heads of the metatarsal bones, should not be injured.

The **tendon** of the **tibialis posterior** may be felt, and, by inverting the foot, seen, as it extends from behind the tip of the medial malleolus to the tuberosity of the navicular; it crosses the talus immediately above the sustentaculum tali.

In the commonest form of club-foot, viz., *talipes equino-varus*, the tuberosity of the navicular is approximated to the medial malleolus, so that tenotomy of the tendon should be performed through a puncture a little distal to the tip of the medial malleolus; if the knife, after dividing the tendon, is carried down to the bone, the **plantar calcaneo-navicular ligament** will be divided and the **talo-navicular joint** opened, a procedure which is called for before the foot can be brought into good position.

Crossing the front of the ankle-joint, from medial to lateral side, are the following tendons, viz.: the **tibialis anterior**, the largest and most prominent; the **extensor hallucis longus**, the **extensor digitorum longus**, and the **peronæus tertius**. The **extensor digitorum brevis** gives rise to a fleshy pad which overlies the dorsal aspect of the calcaneo-cuboid joint. When the foot is everted, the tendon of the **peronæus brevis** may be seen extending from the tip of the lateral malleolus to the base of the fifth metatarsal bone; immediately below it is the tendon of the **peronæus longus**, which, as it winds round the cuboid, is obscured by the fleshy fibres of the abductor digiti quinti muscle. The **abductor hallucis muscle**, although described along with the sole, forms a fleshy pad along the medial border of the foot below the sustentaculum tali.

An incision, extending from the tuberosity of the navicular to the middle of the medial border of the heel, will expose the various tendons, vessels, and nerves, as they pass from the medial malleolus into the sole, beneath the abductor hallucis.

The **dorsalis pedis artery** may be mapped out on the surface by drawing a line from a point opposite the ankle-joint, midway between the tips of the two malleoli, to the posterior end of the first interosseous space; the vessel may be compressed against the medial column of the tarsal bones. The **great saphenous vein** and the **saphenous nerve** lie between the anterior border of the medial malleolus and the tendon of the tibialis anterior; the **small saphenous vein** and the **nervus suralis** take the same course as the tendon of the peronæus brevis.

The **medial plantar vessels** and **nerves** lie along the **medial intermuscular septum**, which corresponds to a line drawn from the inferior surface of the medial tubercle of the calcaneus to the interval between the first and second toes. The **lateral plantar vessels** and **nerves** may be exposed by an incision along the **lateral intermuscular septum**, which runs in a line extending from the middle of the inferior surface of the heel to the fourth toe (Kocher); to map out the course of the **plantar arch**, draw a line across the sole from the medial side of the base of the fifth metatarsal bone to the proximal end of the first interosseous space.
